The treatment of mental disorder, whilst comprising all the methods employed in the relief of physical disease, has of necessity to include much more, and the psychological element must, in most cases, bulk largely in all therapeutic measures for the relief of mental illness, both in the mode of treatment and in the supervision and control of employment of direct suggestion. It is only necessary to compare the amenability of a medical or surgical out-patient department with that of a mental out-patient clinic to appreciate the difficulties which confront the physician when treating out-patients those suffering from mental disorder. In the third annual report of the Maudsley Hospital Dr Mapother, the medical superintendent draws attention to this difficulty. "In regard to treatment proper," he says, "it remains true that available methods are equally indispensable to the real efficacy of an out-patient clinic. In their absence such a department receiving a mixed clientele would be reduced to the absurd position of being quite impotent in respect of a large part of its out-patient cases. It would be easy, and in the present state of public feeling very dangerous, to exaggerate the extent to which out-patient treatment alone will suffice. The frequency of such treatment alone is confined to a relatively small class of 'functional' cases. In general it may be said that out-patient treatment (by which most out-patients receive psychotherapy) may be adequate (for example in the case of those with a purely obsessional) or even possible (as in many cases with a large element of chronic hysteria) but it is generally quite inadequate for patients with a severe and considerable disturbance of emotion or activity and to say apart from whether such disturbance renders the patient dangerous to himself or others." So it comes that the employment of intensive psychotherapeutic treatment is restricted in a large number of cases, is necessarily limited to a small number of chosen patients who for one reason cannot be admitted, but who are otherwise of exceptional promise. If, however, the treatment of mentally disturbed patients is impracticable on a large scale in an out-patient department, and has perhaps fallen short of the expectations which may be held of it, the treatment of such patients in the wards of such a hospital as the Maudsley holds out bright promise for the future, both as regards the enlargement of our knowledge of mental disease and the treatment of its many manifestations. We have come to consult the Maudsley annual reports as an authoritative source of information, both in the matter of diagnostic measures and therapeutic measures in the treatment of mental illness, and all the more so that Dr Mapother has from the first assumed a modest scepticism of outlook which makes us accept unhesitatingly his positive findings. The treatment employed at the Maudsley Hospital includes general treatment by established methods, and special treatment, much of which, although experimental, raises great hopes. Amongst the established methods of treatment carried out are hydrotherapy, physiotherapy (including Swedish drill, massage, and special exercises such as Fenchel's), electrotherapy, and special and occupational therapy. Among the methods of treatment used recently are the induction of relapsing fever in neurosyphils, the infective material was supplied to Dr Golla, director of the pathological laboratory, by Dr Plant of Munich. It is too early yet to speak of results. In the meantime Dr Mapother is content to observe that the prognosis of all forms of neurosyphilis is being modified as a result of treatment by induced pyrexia and by trypanamide, he favours a combination of the methods. Ultra-violet radiation has been followed by improvement in a number of cases. Of the various medicinal preparations which have been employed, ergot has brought about considerable benefit in cases with anxiety symptoms, and callosol, manganese and afoenol (a preparation of calcium chloride

combined with urea) are being tried, but so far without definite results. Somnifen has been extensively used, and as, in Dr Mapother's opinion, the best diurnal sedative for seriously agitated and hallucinated patients. In such cases it can be so administered by hypodermic injection as to produce a sort of twilight sleep. The complete recovery of confused and hallucinated cases after particularly long treatment with somnifen has convinced Dr Mapother that its use is not attended by the risk of producing dementia. Dr Mapother, Dr Golla, and their colleagues and helpers are tilling a difficult field. Positive results are not easy to come by, but their courage and skill are such that we believe a rich harvest awaits them and us.

## THE ORTHOPAEDIC HOSPITAL IN LONDON

WARREN the spacious and then new out-patient department of the Royal National Orthopaedic Hospital in Bolsover Street, Marblebone, was opened in 1909, it was not anticipated that within twenty years it would be found quite inadequate. But at that time the out-patient attendance numbered only 16,235, and, although the provision made for increase then seemed generous, no one concerned foresaw that in 1926 those attendances would have increased to 77,559, or nearly fivefold. Not only are the attendances more numerous, but the need for more accommodation for treatment has increased in a greater ratio, seeing that in this, as in other hospitals, great developments have taken place in the last eighteen years in the scope of electrical physiotherapeutic methods and of the application of radio-graphy. In 1909, moreover, the hospital possessed no workshop of its own, but was dependent upon instrument maker for all the appliances required by patients. Despite all the advances in the operative treatment of deformities a very large number of cases need retentive or corrective appliances after treatment, and these must be supplied before, or at least as soon as, the surgeon's work is done if the good gained is to be kept. Such considerations convinced the committee of management of the hospital that they must establish their own workshop, where appliances could be made or modified under the direct supervision of the surgeon or other hospital officers. An extension of the site in Bolsover Street was obtained from the ground landlord, who was then Lord Howard de Walden, but at the juncture the war put a stop to all building on it for some years, soon after the peace a temporary workshop was established with the help of the Ministry of Labour, in which a number of disabled pensioners were trained rapidly and successfully in surgical bootmaking. With the support of the King's Hospital Fund the adaptation of the old out-patient department as a part of the new building was undertaken, and the whole work has been carried to completion at a cost of £58,500. It is in this addition that the president of the hospital, Prince Henry, K.G., will receive the Lord Mayor and sheriffs when, on November 22nd, the Lord Mayor will declare the department open. The spacious and airy out-patient waiting hall is decorated in a manner unusual in such places. Bold designs in colour representing the twelve months of the year, painted in oil on canvas and waxed, relieve the monotony of the walls, and give the too often weary eyes of the patient or his or her friends something pleasant and beautiful on which to rest. The artist, who presented the pictures, is Miss Nan West. The surgeon's room, dressing rooms, and other necessary apartments open on to the hall, which is well lighted from above. There is a well equipped out-patient operating theatre, as well as accommodation for massage, the application of plaster, Pains, exercises, electrical treatment, light treatment, and x-ray work. The provision made in 1909 for the radiograph department soon proved absurdly inadequate. It is hoped that the accommodation and apparatus now provided

this department may be sufficient for all needs for years to come. The very well equipped and extensive workshop is placed in the basement, and affords facilities for a greatly increased and improved production of surgical appliances and boots. Thus remodelled and enlarged out-patient department remains in communication by means of a tunnel under Bolsover Street with the main building and its 200 beds in Great Portland Street, which was opened by King Edward and Queen Alexandra in 1909. This also had become quite inadequate to the needs of the hospital, and soon after the war the responsible authorities decided that more beds were urgently needed, but that it would be unwise to attempt to provide them on a costly site and in the gloom of a great city. The country branch at Brockley Hill Stanmore was the outcome of this decision. This is placed in an ideal situation, 400 feet above the sea, and, although only ten miles along the Watling Street from the Marble Arch, in quite rural surroundings. Besides the old country house and a wooden open air ward, permanent wards for open air and sunshine treatment have recently been built and are on the point of completion, as well as a new surgical block, provision is made also for the most up-to-date treatment of surgical tuberculosis and other crippling maladies, thus raising the number of beds now available here to 266. These extensions have cost over £80,000, and, taken together with the new out-patient department they have involved the charity in a debt of some £40,000. Three-fourths of the patients treated at the two hospitals are children, whose needs appeal with peculiar poignancy to the charitable, and it is hoped that this debt will be cleared off as soon as the needs of the institution are realized by the public.

#### SOME EFFECTS OF LIGHT

A CONTRIBUTION to the knowledge of a subject of considerable general interest has recently appeared in an article by J. V. SUPNIEWSKI, from the Pharmacological Laboratory, Cambridge published in the *Journal of Physiology* (October, 1927). It is on the action of visible light on organs sensitized by haematoporphyrin. The action upon the tissues of short wave length rays is becoming a subject of greater and greater interest, from the point of view both of theory and of practice. Visible light, on the other hand, has been shown to exert little action upon animal tissues, though, in the plant world, the phenomena of photosynthesis have long been familiar. It has, however, been shown that fluorescent substances such as eosin which give off rays of shorter wave length than those which they absorb can "sensitize" tissues and other material (for example, photographic plates) to light rays which in the ordinary course of events would exert no action upon them. The researches of Garrod in this country and of Günther and Venck in Germany, have placed the haemoglobin derivative haematoporphyrin in this category. Itself a fluorescent substance, it can be prepared in the laboratory, while its production in large quantities in the body gives rise to the disease variola vacciforme classed by Garrod among the "inborn errors of metabolism." Supniewski has shown that mammalian tissues can easily be sensitized to visible light by a comparatively brief immersion in Ringer's solution containing haematoporphyrin in strengths of 1 in 20,000 to 3 in 500,000. Although neither haematoporphyrin alone (unless it be in strong solution) nor light alone has any detectable effect, yet when exposed to light after being sensitized by haematoporphyrin isolated portions of rabbit intestine or uterus go into strong tonic contraction and die within half an hour or so. Similar effects are observed on the isolated heart. In the whole anesthetized animal intravenous injection of haematoporphyrin followed by exposure of the viscera to light results in violent contraction of the exposed organs rise of blood pressure, and finally death. The

injection of haematoporphyrin into normal albino rabbits, whose skins are unprotected by pigment, is also followed by fatal results. The author gives reasons for thinking that, in the case of haematoporphyrin, yellow light provides the most effective stimulus. The explanation of these phenomena is unknown. Undoubtedly they are of a general nature and fundamental importance. For their complete elucidation it may be necessary to await the application of the methods of molecular physics to the problems of biology.

#### ON OBSERVATION

MR. ERNEST B. WAGGETT delivered the annual address to the post-graduate class at the Central London Throat, Nose, and Ear Hospital on November 11th. His subject was "Observation," but he began with some general encouraging remarks, one of which was that while, in every generation, there were men who carved out for themselves a great position although everything was against them, in most careers good fortune was a large element. He could name men whose careers had been made by such a chance circumstance as standing at a particular door at a particular moment. The men upon whom fortune thus smiled had, of course, great qualities, and proved themselves capable of rising to the occasion, but it was likely enough that almost any of their less fortunate fellow students would have done equally well in the same circumstances. To watch the face of fortune for its fleeting smile was not a bad piece of advice. The qualities and activities which made up a surgeon could be, and duly were, nullified by the lack of acute observation. No man could be a great surgeon without the ability to perceive correctly. At the same time he begged students not to be discouraged when an error in observation had been proved against them. Such errors occurred in the best possible circles in the region of surgery in which he and they were interested. There were special pitfalls in that branch of surgery for example, the illumination that had to be employed, and the fact that images observed in a mirror were reversed. Incidentally he pointed out that it was an error to suppose that with monocular vision distances could not be judged. True, it was not so easy and natural to judge distances by monocular as by binocular vision, but it was perfectly feasible if only a clear image were fixed of first one and then another part of the picture. The phenomenon of parallax helped in this judgement of distance. He challenged students newly entering his branch of surgery to observe quite clearly and definitely any of the anatomical appearances of the ear nose and throat. He did not believe that during the first two months of such study 50 per cent of accuracy would be achieved. The newness to the students of the objects examined would, of course, at first be a help to observation rather than a distraction, but pre-entail familiarity would tend to produce sickness and would conflict against accuracy. Scarcely any artist could draw his wife's face without making her sit for her portrait, whereas he could draw a recognizable likeness of a railway porter whom he had seen for only a minute. Sargent's method was to stare at his subject for half an hour and then work at the canvas until that cupful of memory was exhausted after which he had another long drinking in of his subject. In surgical work this creation of an image in the memory was almost always essential, with the added difficulty that the inspection must be fleeting in time and all the more concentrated in intensity. Mr. Waggett urged the importance of not looking at too many cases in the hour. The out-patient room could create a world of heresy. A few cases should be concentrated upon, and the rest given a placebo with an order to return. A hasty examination was a thousand times worse than none at all. One cause of inaccurate observation might be defects of vision. Possibly glasses might be needed, and it

was worth while to make a point of that if mistakes were frequent. He urged also the employment of magnification. The small terrestrial telescope he thought to be one of the most valuable adjuncts to the bronchoscope. But, whatever the opinion about magnification, there must be clear, precise vision of every point. Besides unimpaired visual perception there were intellectual causes for wrong observation. Preconceived ideas of things were a fruitful source of error. It would be absurd to say that there must be no preconceived ideas, but in this region of surgery there is no normal typical appearance of structures, except perhaps the ossicles of the middle ear. Another extraordinarily potent source of error was anticipation of what one was to see. The habit of correct observation for any of these reasons had hindered the progress of medicine and surgery. To his own generation it seemed a thing incredible that it should have been left to Meyer of Copenhagen to discover adenoids. If a body of men whose general knowledge already gave them competence in the manipulation of patients would make a daily practice of complete detailed observation, some of them would almost certainly alight upon one of those chances which, when appreciated, led to a great stride in medical progress. Such studies had often come through chance observation. Thus did Röntgen discover X rays and Richet anaphylaxis. The most secure and the simplest method of becoming a great observer was to reduce the observations to drawing or writing, by which he made out nothing more than the case sheet. He also urged men to work in couples, and compare notes, and to avoid over-division, which might lead to re-examination. In conclusion, Mr. Wiggott reminded his audience that while accurate observation was essential to success, in itself it had nowhere. Observation, unless digested by contemplation and illuminated by insight, did not bear fruit. Moreover, while there was an observation which was microscopic there was also another kind of observation, made from the hilltops. It was in this wide outlook—though they had the power of microscopic envisagement as well—that Darwin, Pasteur, and Lister excelled, and thereby changed the whole surface of scientific thinking.

#### OLD MEDICAL BOOKS

As often happens about this time of the year, there are a number of rare and curious old textbooks being offered for sale in the principal London auction rooms. The sale of the Holford library at Sotheby's early in December includes a few first-rate examples, many of them in superb old binding, valuable in themselves apart from their contents. There is a first edition (Venice, 1528) of Paulus Aeginetii's *Opera medica*, an Aldine product. From the same printer, and the same year, is a copy of Celsus's *Medicinarum libri VIII*, in a very fine sixteenth century French binding. Another Aldine, in five volumes, is the works of Galen, 1525. There is also a Hippocrates of rather later date, Leyden, 1665, two volumes. More interesting than any of these is the first edition of Nicholas Leoniceus's *De Epidemia quam vulgo morbum Gallicum vocant*, the first printed work on syphilis, published at Venice by Aldus in June, 1497. In another collection, which Messrs. Hodgson are selling while this note is in the press, the following are noticeable: Michael Scott, *Physiognomica et de Procreatione*, about 1510, Galen, *de Morbis Cruribus*, Leyden, 1546, *Phlegmatism* (presumably a pseudonym), *Thesaurus de Remediis secretis*, Leyden, 1555, Tagantius, *de Chirurgia Institutione*, Leyden, 1567, Argenterius, *In Artem Medicinalem Galeni*, Paris, 1578, Stempnus, *de Morbis Internis*, Leyden, 1587, Ambroise Paré, *Opera Chirurgica*, Frankfurt, 1594, Mackenzie, *De Humanae Rationis Imbecillitate*, 1690—a curiously modern-sounding and provocative title, de Honppeville, *La Generation de l'Homme par le Moyen des Oeufs*, 1676—can this possibly be an anticipation of "Omnis Cellula de Cellula"? There are also

Belloste's *Hospital Surgeon, or a New, Gentle, and Easy Way to Cure Speedily all Sorts of Wounds*, 1701, and amongst a number of pamphlets, J. Browne, *Icterus Against the Circulation of the Blood*, 1701, Proceedings in the Management of Chelsea Hospital (appointment and dismissal of S. Lee, surgeon), 1753, Oliphant, *On the Usefulness of Vomiting in Fevers*, 1699, and many others.

#### SUPERANNUATION FOR LABORATORY ASSISTANTS

We are glad to learn that the London School of Hygiene and Tropical Medicine has adopted a superannuation scheme for the technical and laboratory assistants in its employ, who are grouped in definite grades, each with its scale of salary. As the Federated Superannuation Scheme for Universities does not embrace technical and laboratory assistants, the board of the school has drawn up a scheme for their benefit on the same lines and using substantially the same machinery. The scheme does not apply to any member of the staff whose remuneration is £100 per annum or less, it is optional for those with salaries from £100 to £160, beyond that it is compulsory for all new entrants. An amount equal to 15 per cent of the salary (5 per cent contributed by the employee and 10 per cent by the board) is to be applied in payment of a yearly insurance premium to secure either an annuity on retirement if the age of 60 or a lump sum under an endowment insurance policy. The memorandum embodying the scheme contains a proviso that any member transferring to another medical school or to another institution shall take the benefit of his own contributions and those made by the school. If he leaves the service altogether within five years of joining it he takes the benefit of his own contribution only, but if he leaves after five years he takes the benefit of both contributions. Provision is made also for members remaining in the service of the school after they attain the age of 60. The inauguration of this scheme, which we can well believe has been received with expressions of gratitude from those to whom it applies, should improve the status of laboratory assistants, and it is to be hoped that comparable institutions will adopt similar schemes, and thus pave the way for reciprocal arrangements in the case of transfers and promotions within the service.

#### NOBEL PRIZES

THE award by the Karolinska University of Stockholm of the Nobel prize in physiology and medicine for 1926 to Professor Johannes Fibiger of Copenhagen has now been officially announced. Professor Fibiger is best known to the medical profession for his work on the experimental production of cancer in rats. He succeeded in producing growths of the stomach and tongue by feeding the animals with cockroaches infested with a small nematode. The growths occurred in association with the impregnation of the worms in the tissues, this was, we believe, the first instance of the experimental production of cancer otherwise than by inoculation. The same University has awarded the Nobel prize in the same subjects for 1927 to Professor Julius Wagner von Jauregg of Vienna, who introduced the systematic use of infections with benign tertian malaria in the treatment of general paralysis of the insane, a method which has now been extended to certain other chronic nervous disorders.

We have already announced that the twentieth anniversary of the publication of Harvey's epoch-making book, *De Motu Cordis*, will be celebrated in London under the auspices of the Royal College of Physicians next spring. The date fixed for the celebration is from May 14th to May 18th. Invitations are now being issued, and it is expected that delegates from all countries will then gather in London to offer their tribute to the memory of the first and greatest of physiologists.

The David Lloyd Roberts Lecture  
ON  
CRIMINAL LAW AND INSANITY  
BY  
LORD HEWART

THE fifth David Lloyd Roberts Lecture was delivered on November 16th at the house of the Medical Society of London by the Right Hon Lord Hewart Lord Chief Justice of England, who took as his subject "Criminal law and insanity." Mr Herbert W Carson, President of the Society, was in the chair, and there was a very large attendance.

Lord Hewart began by remarking that the medical and legal professions seemed to have so much in common, and to be devoted in so unusual a degree to the public welfare, that any real misunderstanding between them upon a matter of public importance would be much to be deplored. Yet from time to time there were indications of a lack of complete harmony in the views with which the two professions respectively regarded or tended to regard, the attitude of the criminal law towards insanity. The true description of the subject-matter of that difference, or apparent difference, was of no small importance. The subject-matter was not insanity, but the attitude of the criminal law towards insanity. It was natural enough that the two professions should regard insanity from somewhat different points of view. That circumstance, far from being matter for regret was matter for satisfaction. What was to be regretted was a difference of view upon the actual and the proper attitude of the criminal law towards insanity.

*The Defence of Insanity Conditions it Must Satisfy*

The leading principle of the criminal law of England relating to insanity was still to be found in the answers given to the House of Lords by the judges in the *M'Naghten* case. Every man was presumed to be sane, and to possess a sufficient degree of reason to make him responsible for his acts until the contrary was proved to the satisfaction of the jury. In other words, the burden of proof, where insanity was pleaded, was upon the defence. It was not for the prosecution to establish the sanity of the accused, that was presumed. It was for the accused to prove if he could that at the material time he was within the meaning of the criminal law insane. The word was "prove," not "suggest" nor "indicate" nor "insinuate," nor any such word. Nothing short of proof was sufficient. In order to establish a defence on the ground of insanity it must be clearly proved that at the time of committing the act the person accused was labouring under such a defect of reason from disease of the mind, that he did not know the nature and quality of the act he was doing or if he did know it that he did not know he was doing what was wrong.

The meaning of these words was sufficiently plain. The crucial time was the time of committing the act, not some other time earlier or later. The sufficient defence of insanity, related to that time, must satisfy three conditions: the first two of which were in every case obligatory, while as to the third there was a choice of alternatives. It must be proved (1) that the accused was suffering from disease of the mind, and (2) that in consequence of that disease, he was labouring under a defect of reason. It must further be proved that that defect of reason was one of two particular kinds: and it was here that the alternatives arose. The defect of reason due to disease of the mind, must be clearly proved to be such as either to prevent him from knowing what he was doing or from knowing that he was doing what was wrong. The defence was not required to prove both these conditions, but it must prove one of them.

*Different Standpoints of Physician and Criminal Lawyer*

This requirement, that the defect of reason must be clearly proved to be such as to prevent the accused from knowing what he was doing or from knowing that he was

doing what was wrong, served to illustrate the difference between the standpoint of the physician and of the criminal law. For the physician, it might be enough to find that the patient was suffering from disease of the mind and was in consequence labouring under a defect of reason. When the two facts were established it might follow, naturally, that the patient needed medical care and attention. But when the question was whether a person was to be excused from responsibility for what appeared to be a criminal act, the law insisted upon further investigation. Disease of the mind would not, of itself, afford an excuse, nor would consequential defect of reason. It must be further established that the defect of reason was of a particular kind and exhibited particular characteristics—that is that at the material time it prevented the accused from knowing what he was about, or, alternatively, from knowing that he was doing what was wrong.

Two tests at least were satisfied by this requirement. It seemed to be manifestly in accordance with justice and good sense, as it was in accordance with the principles of the English criminal law, that a man should be excused from criminal responsibility if, through mental disease, he was at the time of his act in such a state of unreason as not to know what he was doing. This was what was meant by "not knowing the nature and quality of his act." It meant, for example, that he thought he was peeling an apple when in fact he was cutting a throat. The like observation might be made when a man was, through a like cause, in such a state of unreason that, although he knew what he was about, he did not know that he was doing what was wrong. He recalled the case of a middle-aged woman who had strangled her mother in law, laid the dead body on the hearthrug and brought in the neighbours to see how well she had done her "duty." In the second place this requirement had the effect of providing a useful test and criterion which the evidence in the case might well enable a jury to apply. In other words what the prisoner had said or done, and the surrounding circumstances, very often yielded material which helped the judge and jury to perceive whether it was true to say that at the crucial time he did not know what he was doing, or that what he was doing was wrong.

The law did not presume to define insanity. That was a medical question. What the law considered was the conditions which had to be satisfied in order that a person might be excused from criminal responsibility, and that was a legal question. At present that question was answered in accordance with the principles laid down in the *M'Naghten* case. It was possible, no doubt, to find in textbooks, especially in footnotes, passages which seemed to entertain or suggest a broader, not to say a looser view, or perhaps to find here and there a similar passage in the report, whether accurate or not, of an individual summing-up. But the law remained, and it must not be forgotten that as matters now stood it was only the defendant who could appeal to the Court of Criminal Appeal, no such opportunity was open to the prosecution. Nor must it be forgotten that, while the physician tended to regard primarily the interests of his patient, the criminal law was concerned with public security. "When I am invited," said Sir Matthew Hale, "to pity the criminal, I reflect also that there is a pity due to my country." This was not to say that criminal responsibility should be imputed where it did not really exist, but it did mean that criminal responsibility should not be overlooked in those to whom it properly belonged.

*Criticisms of the Criminal Law*

Lord Hewart went on to say that he did not propose to waste time in the examination of the silly, the ignorant, or the captious criticisms which had from time to time been directed against the principle of the English law. There was a kind of controversy called "eristic" which sought triumph, and a kind called "dialectic" which sought truth. No serious person had any concern with arguments which did not seek to elicit and establish what was true. Charlatanism and chicanery, for which there was a rich and attractive field, might be left alone. It would be idle to dwell upon their suggestions, and worse than idle to advertise their authors. On the other hand it was necessary

to examine every argument or representation which did not at the time. The contest was brought to a point five years ago when, after a certain notorious trial for murder, a committee was appointed under a learned chairman, to consider any changes which might be desirable in the existing law where the plea of insanity was raised as a defence. The Council of the British Medical Association tendered evidence. The minutes were fully set out in the extremely interesting and valuable report of the Committee, dated November, 1923. The British Medical Association in substance approved the Rules in the M'Naghten case, but added the qualification that no act should be regarded as a crime if at the time when it was done the person who did it was prevented by defective mental power, or by any disease affecting the mind from controlling his own conduct unless the absence of the power of control was the direct and immediate consequence of his own default.

The Committee so far agreed with the report of the British Medical Association as to recommend (1) that it should be recognized that a person charged criminally with an offence was not responsible for his act when the act was committed under an impulse which he was by mental disease in substance deprived of any power to resist, and (2) that in other respects the Rules in the M'Naghten case should be maintained. Was this not manifestly a fundamental alteration in what he had just described as the third requirement or condition? If accepted it would be immaterial that the prisoner knew what he was about or that he was doing what was wrong; he would still be excused from criminal responsibility if he committed the act under an impulse which he was by mental disease in substance deprived of any power to resist.

#### *The Plea of Uncontrollable Impulse*

This suggestion whatever its merits, was not at all a product of the twentieth century. It was really the ancient and dangerous plea of the uncontrollable impulse, which in practice was so difficult to distinguish from the impulse that was not in fact controlled. The doctrine involved two propositions which were by no means of the same kind nor indeed upon the same plane. The first was a proposition of fact—namely that there were unfortunate persons in existence who though they knew what they were about and that they were doing wrong, were nevertheless impelled by diseased and irresistible impulse, to commit an apparently criminal act. The second was a proposition of legislative morality or expediency—namely that these persons by reason of their number or otherwise were of such importance as to require or deserve a fundamental revision of the criminal law. As to the first proposition a man lawyer would hesitate much before he ventured to express an opinion. The proposition belonged rather to the field of medical observation and experience. Let it be granted, for the sake of argument, that persons of this unfortunate type existed. The question remained whether, for that reason, it was just and necessary to make a drastic alteration in the criminal law. The door would be thrown wide open if the alterations were made. The objective tests for judge and jury would immediately and finally disappear. The crucial, the overriding the dominant question would come to be whether the prisoner was acting under an irresistible impulse. Upon what materials and with what guidance would the jury be called upon to answer that question? Would there be any such at all except the medical opinion which the prisoner might be fortunate enough to adduce in his favour, contradicted by the medical opinion offered by the prosecution?

And what were the true dimensions of the difficulty for which so far-reaching a solution was suggested? "It was established," said the report of the Committee already referred to, "to our satisfaction that there are cases of mental disorder where the impulse to do a criminal act increases with increasing force until it is, in fact, uncontrollable." The report here referred incidentally to mothers who were seized with the impulse to destroy children to whom they were normally devoted, but already a special statute which dealt with infanticide offered a

lenient alternative in cases of mental disturbance, falling far short of insanity, where a mother not yet fully recovered from the effects of childbirth destroyed her newly born child. The Committee went on to say: "In practice, in such cases, the accused is found to be guilty but insane." That was a very remarkable statement. It suggested that what was required was already done. If the proposed change in the law were made, the verdict in such cases would be that which was briefly, popularly, and inaccurately described as "guilty, but insane." But this verdict was, it appeared, in practice already returned in such cases. What, then, remained? "We appreciate," the Committee frankly added, "the difficulty of distinguishing some of such cases from cases where there is no mental disease, such as criminal acts of violence or sexual offences where the impulse at the time is actually not merely uncontrolled, but uncontrollable." Yet the far-reaching change in the law was recommended apparently upon the ground that "the M'Naghten formula is not logically sufficient."

#### *The Necessary Stringency of the Law*

Lawyers and statesmen would, he thought, hesitate long before they opened the door to an incalculable flood of mischief for the purely academic purpose of giving logical sufficiency to a formula. But the doctrine or theory of uncontrollable impulse was not in the least novel. It was older than M'Naghten, and might be taken to have been considered and rejected by the judges in that case. In 1859—seven years after M'Naghten—the matter was referred to by Baron Bramwell in *R v Haynes*:

If an influence be so powerful as to be termed irresistible so much the more reason is there why we should not withdraw any of the safeguards tending to counteract it. There are three powerful restraints existing all tending to the resistance of the person who is suffering under such an influence—the restraint of religion, of conscience and of law. But if the influence itself is to be held a legal excuse rendering the crime dispensable, you at once withdraw a most powerful restraint—that forbidding and punishing its perpetration.

In 1863 Mr. Justice Wightman (*R v Buntton*) referred to the doctrine as a most dangerous one, fatal to the interests of society and the security of life. As to the suggestion said Lord Hewart, which was more often implied than expressed, that under the law as it now stood some prisoners were wrongly held to be fully responsible, it might be doubted whether any lawyer knew of any such case. The tendency was the other way—to accept the defence of insanity upon too slender materials. This was regarded as humane to the prisoner, though it paid too little attention to the misery of prolonged confinement in a criminal lunatic asylum. For the security of the public on the other hand, could there be any real doubt that the comparative stringency of the existing law was necessary? After all, the mere fact that a man thought he was John the Baptist did not entitle him to shoot his mother. If a man of abnormally jealous disposition was suspicious of his wife, and his suspicions became what it was fashionable to call an "obsession," was he with impunity to kill her by poisoning, having done all that he could to conceal the crime? In cases where there was evidence of real mental disease, antecedent to the commission of the alleged crime, and there was no evidence of motive which might influence a sane person, juries had no difficulty in finding either that the prisoner did not appreciate the nature of his act or did not know it was wrong. "But if the law were relaxed in the way which has been suggested" (said Lord Hewart in conclusion) "it might well be that, in cases where there has been no such evidence of mental disease antecedent to the alleged crime, mental experts would be found to say that the alleged mental experts would be found to say that the alleged crime itself afforded evidence that it was committed under an irresistible impulse, and that upon that ground the inference might be based that there was mental disease. If so, the result might be to transfer to a section of the medical profession the question whether a great number of ordinary criminals should be held responsible to the law."

# BRITISH RADIOLOGY

WE announced a short time ago that the British Institute of Radiology was about to become incorporated with the Röntgen Society. The incorporation took effect on November 17th, when a general meeting was held at the Central Hall Westminster, and an address was delivered by the President of the amalgamated body, Sir Humphry Rolleston. The following day was given up to discussions in the morning the subjects were x ray and radium protection and x ray measurements, the first subject was introduced by Mr G W C Kaye, D Sc, the second (x ray measurements) was discussed by Professors J A Crowther, D Sc, F L Hopwood, D Sc, and L A Owen, D Sc by Mr C L S Phillips and Professor S Russ, D Sc. In the afternoon there was a discussion on the use of opaque injections as an aid to x ray diagnosis, it was taken under four heads: the nervous system (Sir James Purves-Stewart, K C M G, M D), the urinary system (Sir John Thomson-Walker, F R C S), chest conditions (Dr L S T Burrell), and gynaecological conditions (Dr R A Gibbons). In the evening a dinner was held at the Great Central Hotel, Marblebone. An exhibition of apparatus was open on both days.

## PRESIDENT'S ADDRESS

Sir HUMPHRY ROLLESTON, BART, KCB, MD, FRCP,  
Regius Professor of Physics in the University of Cambridge

THE Röntgen Society, founded in 1897 with the late Professor Silvanus P. Thompson as president and the oldest society which has as its fundamental principle the study of the x rays in their relation to medicine, the arts and sciences, has great traditions and played a notable part in the rise and development of radiology. In 1918 it founded the Silvanus Thompson Lectureship and Medal, the Röntgen Award in 1924 and is associated with the Electrotherapeutic Section of the Royal Society of Medicine in the administration of the Mackenzie Davidson Memorial Lectureship and Medal founded in 1920.

The British Association for the Advancement of Radiology and Physiotherapy (B A R P) founded in 1917 with the late Sir James Mackenzie Davidson as president and Drs R Knox and E P Cumberbatch as secretaries did much good service to radiology in its comparatively short life of seven years, thus it at once took steps to establish a Diploma in Medical Radiology and Electrology and thus was instrumental in getting the University of Cambridge to initiate this in 1920. For this new departure the B A R P worked out all the details of the course and undertook the teaching. It was therefore a most suitable nucleus for a British Institute of Radiology.

The conception of such an institute first suggested by the late Deane Butcher in 1906 was revived in 1917 when a committee of which the late Sir James Mackenzie Davidson was chairman and Dr R Knox secretary was formed, the proposal was taken up with infectious enthusiasm by Sir Archibald Reid who was supported by other leaders in medical radiology. The aims and scope of the Institute were broad. It was to serve as a meeting place of all interested in the subject—medical men in every department of practice, radiologists, physicists, technicians and radiographers, instrument makers and manufacturers—so that it might form a centre for consultation and co-ordination and serve as a bureau to supply information of all kinds to provincial overseas and foreign colleagues, and thus to have an international influence. Although the medical applications of radiology are very important its bearing on industry, arts and sciences and its relations to physics and to biology in its widest sense cannot be too much emphasized, thus in medicine the clinicians, pathologists, anatomists, physiologists and biochemists have much to learn from radiologists who in their turn will reap advantage from an insight into these kindred subjects and close co-operation with colleagues.

In the spring of 1923 a committee with representatives from the Electrotherapeutic Section of the Royal Society of Medicine, the Röntgen Society and the British Association for the Advancement of Radiology and Physiotherapy was formed under the chairmanship first of Dr R Knox and then of the late Sir Archibald Reid with first Dr G W C Kaye and then Dr John Muir as secretary. In April of that year the British Association for the Advancement of Radiology and Physiotherapy became the British Institute of Radiology and obtained the Board of Trade approval of its Articles of Association. It was therefore a most suitable foundation and nucleus for the British Institute of Radiology. Much help was given to the new project by the trustees of the Mackenzie

Davidson Fund who handed over the £1400 collected to the organizing committee. As a result of Sir Archibald Reid's enterprise a long lease was secured of 32 Welbeck Street, and in November 1924, a further, and as it proved somewhat optimistic appeal for £6000 was issued to pay off the bank loan of £2000 and to provide a nucleus for further development.

The objectives of the Institute were set forth as follows: (a) To promote the advancement of radiology and physiotherapy on scientific lines under the direct control of the medical profession protecting in every way possible the interests of those engaged in the subjects; (b) to secure legislative improvements in this connexion; (c) to provide for the delivery of lectures, the holding of classes and examinations, the establishment of scholarship and the granting of prize diplomas and certificates; (d) to arrange for the publication of papers, communications or treatises; (e) to promote and provide for research in experimental work and to establish grants and rewards in connexion therewith; (f) to establish and maintain a library and museum and to organize exhibitions of apparatus; (g) to establish charitable and benevolent funds for the benefit of persons engaged in radiology and physiotherapy.

The Institute opened its doors in January 1924, almost at the time of Sir Archibald Reid's tragic death at any period his loss would have been a very serious blow but at this critical juncture it might easily have been disastrous had it not been for the public spirit of the remaining guarantors A E Barclay and Stanley Melville and for the self sacrificing efforts of Robert Knox, G W C Kaye, Gilbert Scott (honorary treasurer) and others. The Institute weathered the storm, thanks to this help and to the devotion and skill of the secretary Dr John Muir who combines organizing ability with the knowledge of an expert radiologist. This year has seen the amalgamation of the Röntgen Society and the affiliation of the Society of Radiographers to the British Institute of Radiology.

The incorporation of the Röntgen Society and the British Institute of Radiology is a great achievement, it took two years of negotiations to settle the financial considerations and the problems raised by the special interests of the members. It was attained after prolonged discussions between the councils of the Society and the Institute, a revised form of Memorandum and Articles of Association has been sanctioned by the Board of Trade for The British Institute of Radiology Incorporated with the Röntgen Society, and Mr Geoffrey Pearce the successful treasurer of the Pontgen Society since 1915 is to continue to give his valuable services to the amalgamated Institute.

The Institute is governed by a body representing the high contracting parties, equally the interests of each must be respected and maintained—for example purely medical matters must on account of the control exerted by the General Medical Council and for reasons concerned with the educational activities of the Institute as regards the Diploma in Medical Radiology and Electrology of Cambridge, be in the hands of medical members and on this account it is desirable that the Secretary or Director of the Institute should have a wide knowledge of medical regulations.

The Institute now has a roll of more than three hundred active members and fortunately has the support of vigorous branches in the provinces, this is only in keeping with the extraordinary conscientiousness with which country members often from far distant centres, have attended the meetings of the council of the Institute.

Part of the important function of forming a home and centre for all interested in radiology is the existence of a good reference library, which was started by Lady Mackenzie Davidson's gift of the professional library of Sir James Mackenzie Davidson the recognized leader in medical radiology down to the time of his lamented death in 1919. Equally essential is a museum containing a collection of radiographic films and lantern slides illustrating completely the normal and morbid anatomy and physiology of the human body, and also though this is rather for consumption in the future, of comparative radiology.

Just as the Institute helps individual workers and brings them into touch with each other so will it unite for their mutual advantage and strength the various societies concerned with the subject. This alliance will enable joint action to be taken in matters vitally affecting the position of radiology as a scientific profession and the status and interests of the individual workers, thus by the formation of representative special committees on the lines of that on the protection of x ray and radium workers it would be able to express an authoritative opinion on various questions such as the educational requirements to be demanded from those undertaking this work and to consider delicate problems such as the short-circuiting of radiologists when radiographers report direct to medical men and the provision of services by voluntary hospitals to persons outside the classification properly accepted as defining hospital patients. As a centre for teaching it is of great value as has been abundantly proved by the instruction given to candidates for the Diploma in Medical Radiology and Electrology of the University of Cambridge. Further a most

essential object of the Institute, to which effort has yet to be given is research work in experimental laboratories, so that some work may be undertaken and the Institute become the centre of a worldwide organization for systematic investigation of the numerous unsolved problems which most urgently call for elucidation in the interests of mankind. For this purpose endowment to provide research fellowships and grants will be required.

The *British Journal of Radiology* since 1924 has really consisted of two journals—that of the Röntgen Society section, appearing quarterly and that of the British Institute of Radiology section, coming out monthly—edited respectively by Drs G. W. C. Kaye and Robert Knox with a representative editorial board. Now that the amalgamation of the Röntgen Society with the British Institute of Radiology has been happily accomplished these two sections of the *Journal* will be merged in one journal coming out monthly, so that there will be twelve instead of sixteen numbers annually. With these two experienced and enthusiastic Editors, able to call the willing members of the editorial board to regular meetings for consultation or for ready help at any time there can be no doubt that the *British Journal of Radiology* will reflect the combined strength of the united body. It has already done much for the Institute in several ways and special mention must be made of the self-denying abstinence whereby funds which might have been spent on improving the *Journal* have been devoted to the upkeep of the Institute.

The Society of Radiographers which became affiliated to the Institute in January 1927 was formed in 1920 with the assistance of the Institute of Electrical Engineers and the British Association for the Advancement of Radiology and Physiotherapy in order to give a definite professional status to those certified non-medical assistants who work in x-ray and electrotherapeutic departments. It grants a certificate of membership of the Society of Radiographers (M.S.R.) to those who pass a satisfactory examination. As evidence of the interest taken in the Society of Radiographers by medical men practicing radiology (radiologists) it may be mentioned that the late Sir Archibald Reid and Dr Stanley Melville were its first two presidents and Dr Robert Knox a vice-president. Its Article of Association laid down that

"no non-medical member (i.e. no member who is without the qualifications entitling him to practise in Great Britain and Ireland as a physician or surgeon) shall accept patients for radiographic, radio-therapeutic or therapeutic work except under the direction and supervision of a qualified medical practitioner and any breach of this regulation shall be deemed conduct unfitting the member guilty thereof to remain a member of the society."

In 1924 efforts were made to modify the restriction relating to making diagnostic reports on patients, but the General Medical Council vetoed the modification sent to them. This thorny question has several times been discussed but the Article of Association of the Institute of Radiology Incorporated with the Röntgen Society to which the Society of Radiographers is now affiliated provides that no member or associate who is not a registered medical or dental practitioner shall accept patients for diagnosis or treatment except under the personal supervision of a registered practitioner (Article 12). Further, as the result of the action of the General Medical Council, Section 3 of the Institute of Radiology's Memorandum of Association, which provides for granting diplomas and certificates of merit and efficiency, has been amended by the addition of the following words: "and that the holder of such diploma or certificate is not thereby entitled to undertake the medical diagnosis or treatment of patients except under the personal supervision of a registered practitioner." The medical supervision of the Institute of Radiology Incorporated with the Röntgen Society is bound by the regulations of the General Medical Council, and the present policy of the Institute, which is in accordance with the directions of the General Medical Council, enables radiologists to be united with radiographers for their mutual advantage. But any future change that would render it impossible for medical men to remain members of the Institute would obviously wreck the scheme of the Institute, which is remarkable for its exceptionally broad and democratic character. While there may not be any reason to anticipate such a calamity, it is perhaps well that all possible dangers should be clearly understood.

Sir Humphry Rolleston paid a warm tribute to Sir Archibald Reid. He said: "While welcoming you here to celebrate the incorporation of the British Institute of Radiology with the Röntgen Society our minds must naturally dwell on the memory of Sir Archibald Reid (1871-1924), who is so keenly interested in the establishment of this Institute and to whose personality, tact, and indefatigable energy the Institute owes its present home. To the service of radiology, the future of which he had so entirely at heart, Reid unselfishly gave his time that he should have devoted to the preservation of his impaired health. His painful disabilities were hidden by a light-hearted and kindly humorous manner which made him

a delightful companion, ever alert in mind and body and withal somewhat elusive. During the war he was president of the War Office X-ray Committee (1914-19) responsible for the x-ray arrangements for the British forces at home and abroad, and evolved out of chaos a most complete and satisfactory service for our armies on every front—a problem of enormous importance, but sorely and hindered by tiresome obstacles. He had vision, initiative, and a way with him of overcoming difficulties. To Archibald Reid British radiology owes much and to remind future generations of this debt the British Institute of Radiology might well place his portrait, painted and presented by his attached friend C. E. S. Phillips in the museum on the hall to be called after him, the like of whom we shall not see again but the memory of whose stimulating personality will long remain an inspiration."

## THE MEDICAL ASPECTS OF CONTRACEPTION

The National Council of Public Morals established, with official recognition, an inquiry in 1913 which became known as the National Birth Rate Commission, and issued a report in 1916, and a second in 1920. In 1921 it appointed a Special Committee on the Prevention of Venereal Disease, and since then has continued to be extremely active, thus it appointed another and a strong committee under the chairmanship of Mr. Charles Gibbs, which has now issued a report on *The Medical Aspects of Contraception*. This committee of fourteen authorities included several of the contributors, such as Sir Arthur Newsholme, Professor Leonard Hill, and Dr. A. B. Giles, to the work entitled *Medical Facts on Birth Control*, which was reviewed in our columns on March 12th last, edited by the Rev. Sir James Marchant, the general secretary of the committee on the medical aspects of contraception. Other members of the committee are Mr. C. J. Bond, Dr. A. J. Chalmers, J. S. Faubman, C. Porter, H. R. Spencer, Mr. A. Dunnett, M.B., Miss Frances Ivens, M.S., and Dr. I. H. A. Marshall, who also gave expert evidence on the vitality of the spermatozoon and the unfertilized ovum in the female generative tract. The committee held eighteen meetings, and had the advantage of evidence and statements from thirteen medical or physiologically minded men and women including Dr. R. L. Dickinson, a former president of the American Gynecological Society, and the president of the Committee on Maternal Health, New York secretary of the Committee on Maternal Health, Dr. Gestin, of which he is described by another witness, Dr. George Sturges, also of New York, as "a more radical member" as compared with his "extremely conservative" colleague, Dr. G. W. Kosmick, the editor of the *American Journal of Gynecology and Obstetrics*. Dr. Sturges, while regarding some results of contraceptive methods as worthy of attention, did not consider that there was at present sufficient evidence to decide "as to the best method or the desirability for a medical man to follow." Dr. Donn Hare's evidence, based on 4,000 cases seen in six years though not printed in full, occupies more than twenty pages, or a ninth part of the volume, and goes in detail into the technique and value of the various contraceptive methods and appliances. He recommends the use of the occlusive pessary with a jelly containing lactic acid as the failures with this combination proper carried out were not more than 5 per cent. The rationale of this method is that the normal acidity of the vagina, due to lactic acid produced by Doederlein's bacillus, destroys spermatozoa, that this acidity is neutralized by alkaline mucus poured out during the orgasm, and that the alkali may be counteracted by supplying more lactic acid. Many douches in use destroy this bacillus, and, moreover, some, such as lysol, mercuric, and hypochlorite, may set up inflammation. Lord Dawson, in his vigorous terms, stated the case for contraceptive methods criticizing other lines of birth control, and gave his opinion that the use of contraceptives as such has not been proved to be physically or mentally harmful. Crichton Miller agreed with Lord Dawson, and reduced the criticisms of contraceptives to the one heading of wanting to give complete freedom to the community in

<sup>1</sup> *Medical Aspects of Contraception* being the Report of the National Council of Public Morals, appointed by the National Council of Public Morals in connection with the investigations of the National Birth Rate Commission. Martin Hopkinson and Co., Ltd. 1927. (Pp. xiv + 104. 6d.)

matter of sex relations because of the risk of abuse. Dr Alice Robson said that when she went to the Cambridge Birth Control Clinic she anticipated that the wrong people might come for information, but that this did not occur. Mrs Cox, medical officer at the Wilworth Birth Control Clinic, and Mrs C J J Winter of the Wolverhampton Birth Control Clinic also gave evidence. The results of many hundred experiments on rats and on 250 mice in connexion with the comparatively new vitamin L and sterility as a deficiency disease were set out by Mr T A Webster, who was working in Professor Leonard Hill's laboratory, the wheat germ is the richest in this vitamin which also occurs in animal tissues, especially muscles, it is interesting to hear that this deficiency disease affects the sexes differently, it eventually destroys the male germ cells, but does not impair the ovary or ovulation, though causing a characteristic disturbance in gestation so that the foetus dies and is absorbed. Dr Bunnie Dunlop, honorary medical secretary of the Malthusian League, Dr C Killick Millard is a medical officer of health, and Dr R A Gibbons as an obstetrician provided further information to the committee.

The subject of birth control and contraceptives is beset with difficulties but is most important, and the committee selected to represent various views and having much evidence from different angles must have had a hard task to draw up even the conclusions which they all signed but in addition to their unanimous report there are three memorandums, and under them no fewer than seven out of the twelve signatures to the unanimous report are attached. The main body of the report is medical, and not concerned with ethical considerations, and its conclusions are not very startling, thus it will not surprise many to hear that the prevention of conception is being attempted by a large number of individuals and that this number is increasing rapidly, that operative measures, such as destroying the continuity of the vas deferens or Fallopian tubes are usually successful if correctly carried out on that abstinence while it is the obvious, and from the ethical point of view the ideal procedure, when it is desired that no children should be born is impracticable to the majority of young married people. The committee are definitely of opinion that strictly there is not any 'safe' period, though the chances of conception are materially less from about the eighteenth day after the first day of the preceding period until the end of the cycle, that in the close relationship of married life the effects of continued abstinence may be grave for persons of certain temperament and that the entirely successful contraceptive one that is sure, harmless, and simple, has not yet been discovered.

The committee would appear to realize that they have not reached the seal of finality on the contentious subject of contraceptives, as in one place their report is spoken of as an interim one.

## VOLUNTARY HOSPITALS IN GREAT BRITAIN

### EIGHTH ANNUAL REVIEW

The eighth annual report on voluntary hospitals in Great Britain (excluding London) for the year 1926 has been compiled by Mr R H P Orde, director of hospital services Joint Council of the Order of St John of Jerusalem and the British Red Cross Society. It has an introduction by Sir Arthur Stanley chairman of the Joint Council and may be obtained from the council's office 19, Berkeley Street, W 1 price 1s 6d post free.

The report summarizes the financial position of 755 hospitals and the work done in the year under review. Analyses are provided of the sources of ordinary income and principal items of expenditure. Other subjects dealt with are the function of the voluntary hospital in relation to the public health service as detailed in the paper read before the British Hospitals Association in June by Sir Arthur Stanley, the relation between voluntary hospitals and institutions provided by public authorities, and the importance of the almoners

department, the address delivered by Sir Berkeley Moynihan at the meeting of the Institute of Hospital Almoners in May being incorporated in the report.

### Financial Position

During 1926 the total receipts of the hospitals under review amounted to £7,916,816, the expenditure on maintenance and development was £7,666,596, leaving a surplus of £249,220. The number of hospitals with a credit balance on their maintenance accounts was 67.23 per cent of the total. The income fell as compared with the previous year by £222,404, while the expenditure rose by £546,506. Mr Orde has calculated that this relative deficiency of £768,910 denotes that each hospital but was poorer by £16 8s 4d, or rather less than 1s a day. He draws the conclusion that, although the total burden of the hospitals' deficit may appear heavy, it could be quite easily borne if well distributed. In order to obtain a more accurate survey of the financial position of the provincial voluntary hospitals, new tables have been introduced into the report this year with a view to showing whether the income was sufficient to meet the maintenance expenditure during that period. In previous reports it has never been possible to state definitely the number of hospitals which would be found to be paying their way if the extraordinary income and expenditure were taken into account. The new method of analysis elucidates this matter, and the results are illustrated by coloured diagrams. With regard to the extraordinary receipts, the suggestion is made that legacies follow in the train of organized appeals more often than is generally thought—a fact which appears to be better understood north of the Tweed than further south. While 437 hospitals with credit balances received practically one seventh of their income from free legacies, 219 with adverse balances received only one sixteenth in this way.

### General Statistics

The number of available beds in these hospitals was 46,815 and the total number of new inpatients during the year was 683,196. The total number of new outpatients was 2,757,415. These are definite advances over the figures for the previous year. It is estimated that the yearly increase in the volume of work which the voluntary hospitals have to undertake is approximately 40,000 inpatients and 150,000 outpatients. Mr Orde suggests that it is possible so far as the voluntary hospitals are concerned that the shortage of beds is not so serious as the Voluntary Hospitals Commission reported two years ago, but in the last few years the burden of traffic accidents has become increasingly heavy. It is thought that much of the inpatient work which these hospitals are consequently almost compelled to undertake could be equally well performed in less expensive institutions. At one hospital during the year an entire surgical ward of twenty-five beds was continuously occupied by patients suffering from the results of motor accidents whereas five years previously these beds were available for the treatment of ordinary surgical cases from the locality. Moreover, the rate of progress in providing accommodation is retarded at present by the uncertainty as to the future relation between the voluntary hospitals and those provided by the public authorities. The volume of work in the Scottish hospitals appears to have grown during 1926 approximately at the rate of 6 per cent in the case of inpatients and 9 per cent in the case of outpatients whereas the corresponding figures for the English and Welsh hospitals are 8 per cent and 6 per cent respectively.

### The General Outlook

With a view to obtaining information about the future relation between the voluntary hospitals and those provided by public authorities, questions were sent out early in 1927 to administrative officers of several large provincial voluntary hospitals. The inquiry related to the possibility and advisability of defining the spheres of activity of these institutions, the ability of voluntary hospitals to provide the funds to meet their needs within defined spheres, the alleged danger of the voluntary hospital losing its support owing to the existence of similar buildings provided by public authorities, and the devising of a scheme of co-operation which would preserve the character of the voluntary hospitals. Replies were received from responsible authorities in hospitals at Sheffield, Newcastle-on-Tyne, Dundee, Manchester, Oxford, Sunderland, Wolverhampton, Norwich, Chester, and Northampton, these are published, but no attempt is made to collate the results.

## MEDICAL SICKNESS, ANNUITY, AND LIFE ASSURANCE SOCIETY

THE annual general meeting of the Medical Sickness, Annuity, and Life Assurance Society, Ltd., was held at the offices of the Company, 300, High Holborn, W.C., on November 14th, under the chairmanship of Dr. F. J. ALLAN.

### CHAIRMAN'S ADDRESS

THE CHAIRMAN said that the feature of last year's business was that although the amounts insured were greater the actual new premiums were smaller, this was accounted for by the large number of younger men who had joined the society soon after qualification, and were therefore entitled to receive a rebate on the first two years' premiums. While the expenses of the society had fallen, the gross rate of interest had increased. In common with all business concerns the society naturally felt the effects of the strikes of 1926, but on their cessation it recovered ground, with the result that it was one of the few insurance companies able to show an improved position. In a number of cases where members had had difficulties in meeting liabilities previously undertaken, the society had been able to make arrangements to assist them over the trying period. The claims for sickness benefit were above the average, and the influenza epidemic in the spring caused an increased expenditure of nearly £3,000. From statistics prepared by the secretary of the society it appeared that during the four years ending June 30th, 1926, 306 members had undergone operations, major and minor, and the number of weeks sickness experienced in those cases was 2,137, the average duration being six weeks six days. It was found that generally speaking, the greatest number of operations was between the ages of 30 and 50 years. Many grateful letters were received from members receiving benefit as the result of sickness or accident. Dr. Allan found that 24 per cent of the members drew benefit each year, fifty were permanently disabled and had been incapacitated for a long period, in one case a member had drawn benefit for twenty-four years. The importance and value of a permanent contract as compared with an annual one, which might be terminated at any time if a member began to make claims, needed no emphasis. Every endeavour was made to treat members fairly and justly, and the society paid what the member had insured for until he was able to resume work. The life assurance fund showed a steady increase. The excellent value given in the society's combined life and sickness tables had won the admiration of insurance companies. The total new sums insured had increased from £136,810 to £146,025. The rates offered by the society were low as compared with other companies, because they had not hitherto added a loading for the purpose of bonus or payment of commission to agents. To meet the wishes of some members, who were prepared to pay a small additional sum by way of an annual premium in the expectation of receiving a rate of bonus equivalent to that paid by other companies, the society had prepared a list of tables at a slightly higher extra premium, which would provide for a guaranteed bonus in addition to any other bonus which might be declared on the existing rates. The society had introduced a scheme for the assistance of practitioners purchasing houses, and also one to help young members of the profession to enter into practice.

The adoption of the report and audited accounts, having been put to the meeting, was carried.

### Election of Directors and Auditors

Dr. C. BATTAR and Dr. W. K. SIBLEY were re-elected to the board of directors, and Messrs. HAIBER, STUIGESS, and FISHER were reappointed auditors. On the motion of the CHAIRMAN a vote of thanks was accorded to the manager and his staff for their excellent work during the past year.

### Quinquennial Valuation

THE CHAIRMAN, in presenting the quinquennial valuation report, recalled that several members expressed doubts as to the wisdom of changing the society from a friendly society to a mutual company, but he considered that the present report amply justified the course adopted. The greater freedom given under the Life Assurance Companies Acts had contributed in no small extent to the success shown by the valuation. The Life Assurance Fund was being built up slowly but surely. The mortality experienced was only 55 per cent of the actual expected deaths, and the net interest was £4 10s. against 3 per cent assumed in the valuation, which, coupled with the low expenditure, was a source of profit. The surplus thus produced amounted to £21,850, and the cost of the bonus recommended was estimated at £12,117. It was the intention of the society to build up and conserve its resources in every possible way. The rates charged by the society for the "with profit" policies were about 9s. per cent lower than the average of other companies. The Annuity Fund had been valued on the latest

tables, which showed a longevity beyond that experienced on all previous tables. It had, therefore, been decided to strengthen it by a transfer of £3,000 from the reserve fund. A stringent valuation had been made of the Sickness Fund. The actuary had estimated that £245,071 was required to meet the liabilities of the fund, and as the fund amounted to £333,712 there was a surplus of £88,641. Acting on the actuary's advice, it was proposed to distribute £49,640 in the form of reversionary bonuses. As showing the progress of the society since the last valuation in 1922 the chairman enumerated the increases in the various funds, and said that the total funds had increased from £350,000 to £511,000. During the five years £125,000 had been paid to members in respect of sickness and accident, as compared with £98,000 in the preceding five years.

The recommendations suggested by the directors were then put to the meeting and adopted, and, on the motion of Sir WILLIAM WILLCOX, seconded by Dr. HARVEY HILLIARD, a hearty vote of thanks was accorded to the chairman for his work on behalf of the society during the past year.

## England and Wales.

### LORD MAYOR OF LIVERPOOL

THE election of Miss Margaret Berran as Lord Mayor of Liverpool is an event of medical interest because the proofs of her administrative capacity are to be found in works and enterprises closely related to practical medicine. As founder of the Child Welfare Association in Liverpool, she commenced work in a small way, but with fervid enthusiasm, dogged determination, and splendid pertinacity she has developed an association of unsurpassed activity and efficiency. As collateral enterprises, the institution of two hospitals and one convalescent home was almost entirely due to her personal initiative, while the scholars of the special day schools, "tired mothers," and many other groups of poor mothers and children in Liverpool owe much to her. In the development and direction of child welfare work she has done nobly by her native city. She has also been fortunate in a sympathetic and generous environment, and in a contemporary medical atmosphere exceptionally progressive. Nearly thirty years ago Sir Robert Jones and Dr. C. J. Micalister gave practical expression to their desire for therapeutic prophylaxis by obtaining the election of a county hospital with school for long-continued cases, such complete treatment for medical and surgical cases of illness in childhood was among the pioneer movements in the country. With the after-cure work involved Miss Berran's Child Welfare Association was in close touch, as it has always also been with all the activities of the official services in Liverpool dealing with children. The approach to a right appreciation of medicine through welfare work is not easy, but thirty years is a long probation. Miss Berran has proved herself a master in welfare work, and in the less emotional field of medicine it is hoped the coming year will find in her a true friend and a wise condutor.

### COST OF TUBERCULOSIS TREATMENT

A memorandum (122A/T) has been issued by the Ministry of Health containing, in tabular form under various headings, the weekly cost for each patient at certain residential institutions for the treatment of tuberculosis in England and Wales during the year ending March 31st, 1927. For the purposes of comparison the corresponding figures for the previous two years have been inserted when available. It is hoped that this information may assist authorities in deciding whether in a given case the various items of expenditure are on the lowest possible level compatible with efficiency, and so may enable them to administer their institutions economically. Since it is clear that full value for the expenditure incurred at any residential institution can only be obtained if the beds are constantly occupied, it is recommended that all possible steps should be taken to secure that vacant beds are filled without delay by suitable patients, in this respect the co-operation of authorities of other areas is advised. As in previous years the question of the proportion of staff to beds for patients is emphasized, and there are indications that in some institutions this matter still requires careful consideration.

## ALL-DAY VENEREAL CLINIC

The London County Council is being asked by its Public Health Committee to make a grant in aid to the West London Hospital to permit of the establishment there of an all-day clinic for venereal diseases. Such a clinic cannot be satisfactorily provided in the existing hospital building and the governing body of the hospital is prepared to erect a new building for the purpose at a total cost, including equipment, of £13,500. The grant proposed to be made by the London County Council will be £1,500 a year for the period (about thirteen years) necessary for the repayment with interest of a loan of this amount. The arrangements for the clinic will be subject to the annual approval of the Council and of the Minister of Health, and it will be a condition that the building shall be used under the scheme for the diagnosis and treatment of venereal diseases or other approved public health services for at least thirty years. All day clinics have up to now been established at five hospitals in London but the need for such a clinic to serve the western district, for which the West London Hospital is conveniently situated, has been felt for some time.

## Scotland.

## ROYAL SCOTTISH NATIONAL INSTITUTION COLONY

An appeal has been issued by Mr. John Buchan, M.P., in aid of the fund for the establishment of a colony in Scotland for the maintenance and training of mentally defective children. The proposed colony is to be established in connection with the Royal Scottish National Institution at Larbert Stirlingshire. The author of the appeal points out that in the old Scots life the village idiot was a familiar figure that the world of our ancestors where men and women crowded to witness public executions or went in throngs of a Sunday to stare at the lunatics chained up in Bedlam, was an inhumane world but was also a small world where life was slow and simple. In the Scottish rural parishes of former times an idiot had kindly treatment and led a not unhappy life. To-day however there was no room for this casual charity and the mentally defective, if uncared for, were apt to sink to the lowest depths of suffering and degradation. There was now a statutory provision for the care of mentally defective children but the provision ended at the age of 21, when the defective man or woman was cast upon the world. No one who remembered the tenderness with which Dickens had drawn characters like Jo and Maggie, Smike and Barnaby Rudge could contemplate without terror the future of any defective child in whom he might be interested and the world to-day was more intricate and difficult than the world of Dickens. A Royal Commission had reported upon the problem, and the Mental Deficiency and Lunacy (Scotland) Act was passed in 1913. Under that act a responsibility to provide for feeble-minded children was laid on district boards or control. Long before this time the Royal Scottish National Institution at Larbert had been founded in 1862. To-day it housed five hundred juvenile defectives to whose well-being infinite care and thought were given. This institution dealt with three classes—private pupils whose relatives could afford to pay for their maintenance, pupils who were maintained largely at the expense of public authorities, and thirdly, children who did not come under the definition of the Act but who were the offspring of recipients of small fixed salaries who could do little to support them. The latter class of children composed about one-tenth of the inmates and there was a tragically long waiting list for their admission. This large class which lay between the one in a position to pay and the one for whom public authorities were responsible could only be supported out of charitable contributions. In England there were several whole-life institutions for these persons; in Denmark there were farm colonies for the purpose and in some of the American States admirable provision had

been made for such cases, but in Scotland nothing had yet been done. The Royal National Institution, therefore, proposed to establish a colony on a neighbouring estate which it had acquired, where three hundred patients could be accommodated and trained for useful work. This would be the first colony in Scotland for the whole-time care of the mentally defective, and no less than £70,000 would be required.

## ANIMAL DISEASES RESEARCH

The Institute of the Animal Disease Research Association at Moredun Gilmerton near Edinburgh was opened on November 4th by Sir John Gilmour, Secretary of State for Scotland. The Duke of Buccleuch who presided, and the erection of the institute was one of the best things that had ever been done in the interests of agriculture in Scotland, and Sir Robert Greig, Chairman of the Board of Agriculture for Scotland, declared the institute as the spearhead of the attack on animal diseases in Scotland. Sir John Gilmour in declaring the institute open said that this enterprise was initiated by the great stock-breeding interests in the country and that it had arisen by recognition of the necessity for dealing with problems upon which the existence of flocks and herds depended. Scientists, professors and researchers had their place but there was still a difficulty in persuading the practical farmer and stockbreeder that the scientist was doing something for his real advantage. They must realize the enormous loss that fell upon the country every year from disease. It was known that diseased cattle might carry the seeds of trouble in milk to human beings and therefore the idea was growing that research in animal diseases was closely linked up with the progress and well-being of the community.

## VETERINARY TRAINING IN THE WEST OF SCOTLAND

Professor John Glaister, M.D., who presided at the annual prize distribution at Glasgow Veterinary College on November 9th said that 72 students had presented themselves in the past year for examination of whom 45 had passed (62 per cent). Four women students had attended the classes in the past year and it was expected that an increase of women students would take place during the coming session. Eight of the students were studying for the B.Sc. in Veterinary Science at the London University. Last year one of the students of the college, Mr. Thomas Johnston had won the Fitzwilliam prize given by the Royal College of Veterinary Surgeons to the student who obtained the highest aggregate marks in the examinations for its membership. Some difficulty had been caused by the withdrawal of the Government grant to the college on the grounds that there was no room for two veterinary colleges in Scotland. The Glasgow college had however no come to an end, and was to be continued. Lord Provost Macdonald thereafter presented the prizes.

## DR J. S. MUIR OF SELKIRK

Dr. John Stewart Muir, J.P., who is now 83 years of age and began his professional career in Selkirk as long ago as 1867 recently celebrated the fiftieth anniversary of his appointment as medical officer to the Selkirk Parish Council. The occasion was taken to entertain him at a supper in the County Hotel and to present to him a framed and enlarged photograph of the members of the council with himself in the centre of the group. The chair was taken by Mr. Robert Stark, chairman of the parish council, and Dr. Muir, in returning thanks, recalled some of his adventures while attending patients in wild or lonely places, the lonely places of Selkirkshire. Provost Ballin and Dr. Muir as the best loved man in the town and other tributes were paid to his great professional services and his good work in the public life of Selkirk and district. Dr. Muir was chairman of the South Lanarkshire Division of the British Medical Association in 1912 and is a past-president of the Edinburgh Branch. He was formerly surgeon lieutenant-colonel in the Border P.L.I., retiring with the rank of honorary colonel and holding the Volunteer Decoration.

## CENTRAL MIDWIVES' BOARD EXAMINATION

At the examination just concluded of the Central Midwives Board for Scotland, held simultaneously in Edinburgh, Glasgow, Dundee, and Aberdeen, out of 147 candidates 129 passed. Of the successful candidates 17 were trained at the Royal Maternity Hospital, Edinburgh, 48 at the Royal Maternity Hospital, Glasgow, 9 at the Queen Victoria Jubilee Institute, Edinburgh, 7 at the Elsie Inglis Memorial Hospital, 9 at the Royal Infirmary, Dundee, 9 at the Maternity Hospital, Govan, 2 at the Maternity Hospital, Aberdeen, 4 at the Stobhill General Hospital, 3 at the Baishaw Maternity Hospital, and 2 at the County Hospital, Bellshill, and the remainder at various recognized institutions.

## Ireland.

## POOR LAW MILK SUPPLIES

THE Minister for Local Government and Public Health of the Irish Free State has notified that from time to time he has observed that local Poor Law authorities experience considerable difficulties in regard to the quality of the milk delivered under contract to the institutions within their charge, and that legal proceedings under the Sale of Food and Drugs Acts on account of deficiencies of fats or other solids are not always attended with satisfactory results owing to the plea that the milk delivered was in the same condition as when it came from the cow. While this defence may exonerate a contractor from culpable manipulation, it leaves the inmates of public institutions, often invalids and young children, open to receive a milk supply of inferior nutritive value. The question of milk standards was examined by an interdepartmental committee, which recommended that as a means of educating public opinion with regard to differential milk values, local authorities, in placing their milk contracts for supplies to institutions or establishments under their control, should be advised to specify a minimum content of fats and other solids. The Minister concurs in this suggestion, and commends it to the favourable consideration of Poor Law authorities. The minimum specified in the contract should not be below the legal standards of 3 per cent for fats and 8.5 per cent for other solids, but it would be open to the local authority to stipulate for a higher requirement, having regard to the circumstances of the district and to the season of the year. The contract should include provision for a suitable penalty in case of non-compliance. Before accepting a tender the Poor Law authority, if also a public health authority, should arrange for a report on the condition of the premises and on the health of the cattle from their dairy inspection staff. If not a sanitary authority, they should apply to the sanitary authority concerned for similar information. An adverse report would be a sufficient ground for the non-acceptance of the lowest tender.

## Correspondence.

## THE LATE PROFESSOR ADRIAN STOKES

SIR,—I had not yet returned from South Africa when the obituary notice of the late Professor Adrian Stokes appeared in your issue of October 1st, and this and the subsequent correspondence escaped my notice until I re-read my *British Medical Journals* after my return to this country. As I happen to possess accurate records bearing on the subject of Professor Stokes's services at the front in 1914 and 1915, and as my information in this respect is in a sense unique, I venture to submit a few facts, which can be verified from a diary kept by me at the time.

At the end of September, 1914, I was acting as D A D M S at General Headquarters under the D D M S, Colonel O'Donnell (now Lieutenant-General Sir Thomas O'Donnell, KCSI, DSO, etc.). Visiting the hospitals at Braine in this capacity, I was shown several patients who seemed to be undoubted cases of enteric, and I returned to Ferre-en-Tardenois and reported the matter

to my chief, who at once telegraphed to the D M S, then on the lines of communication, asking that a bacteriologist should be sent to verify the diagnosis. Next day Adrian Stokes arrived on his own motor cycle—which he had had the wisdom to bring with him on proceeding to France—and reported for duty. He had been sent off from the lines of communication without any bacteriological equipment whatever, and with no very definite instructions as to what his duties were to be. This was disappointing, but not unnatural, seeing that the rapid change of base consequent on our retreat had considerably disorganized medical services in back areas. With Colonel O'Donnell's permission I at once called on the Adjutant-General, Sir Nevil Macready, and obtained, through his kindness, the sum of £60 to purchase technical equipment. This I handed to Adrian Stokes, and together we drew up a list of requirements, and, with a letter of introduction to the Pister Institute, he started straight away on his journey to Paris. There he purchased a microscope and a certain amount of glassware, and obtained, through the kindness of the Pasteur Institute, an ample supply of media, ready made and sterile. Packing all these items on his motor cycle he started, without any rest, to return to the front, and within a day was back at Braine working at the suspected enterics.

By October 3rd, within a few hours of getting to work, he was able to report that four of the suspected cases, in non-inoculated men, had given positive Widal reactions. On October 8th he sent me a further report recording fourteen positive Widal reactions and three positive blood cultures. This will suffice to show that he had got down to work at once and was already providing us with absolutely definite information. He continued this work at Braine during the remainder of the Aisne battle, and threw a flood of light on the gradual development of enteric in the non-inoculated reservists called up hurriedly to the colours on mobilization.

The true story of the organization of mobile bacteriological laboratories will be found in the article on the "Organization of Pathological Services" by the late Sir William Leishman, in the *Official History of the War* (Medical Services, Pathology), page 9, 1923. The first bacteriological laboratory to reach France arrived at St Omer on October 14th with Lieutenant Rowlands in charge. So great was the success of this laboratory that the director of hygiene determined to have mobile laboratories on somewhat similar lines fitted up for the hygiene department. The first of these latter arrived at St Omer on November 25th, 1914, under Lieutenant Myers Coplins, who afterwards did excellent work in the Second Army area. General Porter is mistaken in supposing that the Myers Coplins mobile laboratory was the first to be constructed, or that it was contemplated in August, 1914. The first laboratory was that constructed by the Lister Institute and which came out under Lieutenant Rowlands.

General Porter may be right in saying that Adrian Stokes took no part in the operations conducted by the medical services in the Second Army area, for dealing with the typhoid epidemic of 1915. The greater part of this work was done by the Friends' Ambulance Unit, acting under the able direction of General Porter and the D A D M S (Sanitation), Second Army, and it is to be hoped that their splendid services and those of two Belgian ladies, who organized a hospital close to Poperinghe, will one day be fully recorded.

It is, perhaps, not unnatural that General Porter should speak of the Second Army area only, but it is well to bear in mind that the Belgian civilians removed from their homes and from General Porter's area had to be dealt with somewhere else. As a matter of fact, they were dealt with, in the first instance, under arrangements made by G H Q at the Convent of Malassise, close to St Omer, where a general hospital was opened for the purpose, under the command of Lieut.-Colonel (now Major-General) Guise-Moore. At this hospital the bacteriological work was carried out by Adrian Stokes and Cecil Clarke, and their efforts for these Belgian patients from the Second Army area were unremitting.

In this connexion I venture to send you a letter received

by me from Adrian Stokes in May or June 1915, in which he gives particulars of no fewer than 1,000 typhoid patients investigated by him. The figures in the letter fully justify publication from the scientific point of view, and I hope that you will find space for it as a vindication of the work of Adrian Stokes in connexion with military and civilian enteries from the Second Army area during the typhoid outbreak referred to by General Porter.

May I add to the remarks of "A F H" a brief word in appreciation of the late Professor Adrian Stokes? Both during the early days of the war and later when, as adviser in pathology, I came into still closer contact with him, he appealed to me as one of the most reliable, original, energetic, and lovable of the officers engaged in bacteriological research at the front. Adrian Stokes's original letter is appended, though undated, I can place it in point of time from my diary. It was written by him in the stress of field work, and is all the more interesting on this account—I am, etc.,

Cardiff Nov 18th

S. LYLE CUMMINS

*Professor Adrian Stokes's Letter*

Dear Colonel Cummins

I have now some numbers that I think will interest you. Of 400 civilians whom I have examined 12 have been found to be carrying 5 are Eberth 5 are B and 2 are A. They are all faecal and all with two exceptions over 45 years one of the exceptions was a child of 5 and the other was only temporary. The other was a woman of 30. Of about 600 troops examined (both faeces and urine) I have got 4 carriers 2 B and 2 Eberth one of the Bs was either precocious or paradoxical they were all faecal. Of about 300 more whose urine only was examined there were no positives. The whole lot of 1,000 were done two ways by direct plating and also in one dilution of brilliant green the dilution which gave the best experimental results. 12 were positive both ways an Eberth and a B were found by direct plating when the B.G. plate was negative and conversely an Eberth and a B were found by B.G. plate when the direct plate was negative. I think that this indicates that it would be better to continue to do both methods but it does not take account of the fact that the B.G. plate is far easier to deal with and generally shows very many more colonies than the direct plate. They were always plated on Endo's medium. I have often had an absolutely pure growth from the B.G.

Now about the blood cultures of 650 done up to date I have had 33 positive. Going through the lists from the base and from your office I have found 11 whom I have bled and found negative who were subsequently diagnosed at the base. Now the cultures are looked at two days running—the first day after in or about eighteen hours incubation and the second after about forty-two so that if they were positive there is not a very great chance of my missing them and yet there is only about 75 per cent of positive results of possible. This is not so good as I had thought it should be and I don't understand it. The cases have not all been traced but three of them were bled within four days of onset and that should have been good enough. Can you suggest the solution? I apologise for this interminable screed.

Yours sincerely

A. STOKES

**MEDICAL CONFIDENCES**

SIR,—Your leader upon the effects of the McCarrick judgment in July last (July 30th, p. 178) gave weighty expression to the feelings of consternation amongst medical men at the prospect of being compelled to betray the solemn trust of their patients at the order of a judge. Since resumption of Parliament I have had the opportunity of conversation with some leading counsel in the House of Commons, and I have received from them very considerable encouragement for the suggestion that I should ask, under the ten minutes' rule, leave to introduce a bill securing, as the minimum concession, privilege from disclosure for communications made by patients to medical practitioners in pursuance of Article II (2) of the Public Health (Venereal Diseases) Regulations, 1916. I have obtained leave for a motion, which is now upon the Order Paper, for Tuesday, November 22nd, to introduce a bill, as follows:

Medical Practitioners Communications Privilege.—Bill to provide that certain communications between medical practitioners and their patients shall be privileged from disclosure in evidence.

and I am promised the support of a number of very distinguished lawyers in the House for a bill securing privilege restricted to the special case of venereal diseases. I should, of course, have preferred unrestricted privilege, and a clause which I had proposed to incorporate in

my bill runs as follows: "Confidential communications passing between a medical practitioner and his patient shall be privileged from disclosure where made for the purpose of obtaining or giving medical assistance in some illness from which the patient is suffering." I am, however, being earnestly dissuaded from attempting this wider purpose by distinguished lawyers in the House, who warn me quite frankly that there would probably be general opposition from lawyers to the enlargement of medical privilege to the same degree as the lawyers now enjoy. If your readers can in any way assist, by representations to their Members of Parliament, the acceptance of my motion on Tuesday, November 22nd the crying scandal of the present position—namely, the conflict between law and regulations in relation to the administration of the venereal diseases clinics might perhaps be removed—I am, etc.,

House of Commons Nov 18

E. GRAHAM LITTLE

**WATER SUPPLY, IODINE AND FOOD IN RELATION TO GOITRE**

SIR,—I was interested to see the letter in your issue of November 12th (p. 897) from Dr. Philip Turton, who, along with Dr. Ash, county medical officer of Derbyshire, has done an enormous amount of work in relation to goitre. His remarks regarding relation of vitamins to goitre are particularly interesting to me, as we have among our measures to prevent goitre, been recommending a diet similar to that advised by McCarrison and noted by Dr. Turton. The following is an extract from my school medical report for 1924:

*General Preventive Measures*

In addition to treatment in the schools the M.O.H. is at present and has been for some time carrying out in water supply and child welfare and school medical work certain general measures which he believes will tend to prevent goitre. The recommending of (a) a special diet containing vitamins and cod liver oil (which contains iodine in minute quantities) (b) cleanliness of habits (c) fresh air and sunshine and (d) removal of focal infections etc. leaflets for expectant mothers, infants, toddlers and school children containing these recommendations are distributed.

A leaflet issued to the parents of children attending school contains the following:

During the period of growth good fresh food with a large proportion of fats and vitamins is necessary. Recently acquired knowledge shows that for proper growth children require food rich in vitamins. These are especially necessary for pale, fatty and rickety children. The following are foods containing these vitamins or essentials for growth and health: Brown bread, eggs, oils (especially cod liver oil), milk, butter, liver, beef, suet and dripping, wholemeal fresh vegetables especially green vegetables such as cabbage, watercress, salad, potatoes, apples, oranges. Salads containing lettuce, etc. and fruit are very good as meals as they help to cleanse the mouth and preserve the teeth. Or all food, milk is the most necessary for a growing child.

We certainly have some decrease in the incidence of goitre in Glossop, but in addition to the advice given above we search for goitre in the early stages and administer iodine in suitable cases. Iodine, however, does not suit every case and in one part of our town with a lead-soluble water supply the administration of iodine appears to have no effect whatever. The causation of goitre is evidently complicated by a variety of factors. Perhaps a deficient diet associated with lack of sunshine may be among such factors, and I think it is wise therefore that we should not rely upon one panacea alone for the prevention and treatment of goitre—I am, etc.,

E. H. M. MILLIGAN, M.D., D.P.H.,

November 2, 1915

**RADIATION TREATMENT OF BREAST CANCER**

SIR,—The average medical man after carefully reading the account in your issue of October 22nd of the discussion at Edinburgh on the radiation treatment of cancer of the breast must, it seems to me, be left in a confused state of mind. On the one hand he reads that the use of massive doses of highly penetrating rays was advocated not only in the inoperable case, but also for post-operative treatment in all cases, including those in which there is at least a fair chance that the patient may do well even if left alone.

It was stated by the opener of the discussion that it was necessary to cause some erythema, and the possibility of subsequent ulceration was admitted. Reference was made also to the occurrence of an "x-ray pneumonia," and a case quoted in which a typical bronchiectasis remained. On the other hand, the inquirer will see that, so far as can be judged from a report of the subsequent discussion, no support was forthcoming for these views.

The general views of British radiologists were, I think, well expressed by Dr. Barclay, and may be summed up in the maxim, *nil nocere*. This applies especially in regards prophylactic-post-operative irradiation. The surgeon, if he has operated on what he believes to be a favourable case—a case which may reasonably be expected to remain free at least for some years—cannot be expected to recommend to his patient any method of after-treatment which involves risks.

Purely prophylactic treatment should take the form of short courses of x rays of medium penetration, given in divided doses spread over a few weeks. Such treatment should produce no visible effect on the skin other than a slight brownning, and, in a patient below par, should have a good effect on the general health. The value of such courses must be judged partly from observation and partly by inference. That many patients remain free for long periods under such treatment is undoubted, but the chief argument in favour of such a dosage system is to be found in the fact that similar treatment may cause the total disappearance of encysted metastatic tumours in some instances, and, in others, render inoperable cases operable. How these results are brought about is not clear. There is certainly no question of a "lethal dose" to cancer cells, although there may be some selective depressant action. Far more important is the stimulation of natural defence mechanisms, both local and general. These courses of x rays should be alternated with treatment by ultra-violet light. All x-ray therapy departments in large hospitals are overburdened with inoperable or recurrent breast cases. My experience is that while some of these patients seem to "live on" x rays for years, others, after a temporary improvement, relapse. The condition of such patients is terrible indeed. They are in pain, they are gradually losing weight, and their physical condition, combined with the fact that their last hope, x rays, has failed them, causes them to fall to the lowest depths of depression. About a year ago, at the Croydon General Hospital, I decided to try the effects of general light treatment on such cases. The results have in many instances been remarkable. The following are brief notes of two cases.

A spinster, aged 42, underwent radical removal of the left breast in January, 1925. Recurrence occurred above the left clavicle and she was operated on again on March 18th, 1927. Several glands were dissected out and the wound closed. She had a course of twelve x-ray sittings during March and April. She was losing weight and suffered from pain and depression. General light treatment was commenced on May 12th, and continued, with one month's intermission, till October 17th. The pain was relieved, the spirits raised and the weight increased by 7½ lb. The patient says—and similar expressions are common—"the sun treatment is life to me."

A spinster, aged 67, four years ago noticed a lump in the left breast, which has since increased in size. There was no pain but the lump had "itched" lately. When examined in April, 1927, the lump was fixed to the ribs, and there were glands in both axillae, also a gland in the right groin, which was removed by Mr. Cowell. The pathologist reported much fibrous tissue with a few small areas of carcinomatous cells. The patient had a course of eighteen x-ray treatments. She was very miserable and was losing weight. She was given light treatment before completion of the x-ray course. The light treatment was continued till August 6th. The patient was now cheerful, and had gained 6½ lb in weight.

There have been similar successes, and also some failures. On the whole, the results have surprised me. The more I see of breast cancer the more I am impressed by the part which general resistance plays in holding it in check. Apparently light can raise this resistance when x rays have ceased to do so. On the other hand, x rays may again have a beneficial effect after a long course of light.

At the French Hospital, and at the Croydon General Hospital, cases are sent for prophylactic x-ray treatment within a few days after operation. I would urge surgeons,

if they are going to send cases at all, to send them soon, and to those surgeons who continue to distrust x rays I say, at least send your patients for repeated courses by general light treatment, to which, if properly conducted, there can be no possible objection on the ground of risk.

In conclusion, I want to make it quite clear that I am a believer in deep or high-voltage therapy in its proper place. In pelvic cancer, in mediastinal invasion, in painful metastases of bone, and many other conditions, it is invaluable when carefully used. I have used it myself for over five years, and have felt the need of it so much in hospital practice that I have recently induced the Croydon General Hospital to equip a special department for this form of treatment. In the post-operative prophylactic irradiation of breast cancer intensive therapy is, however, entirely out of place—I am, etc.,

London W., Oct. 22nd

F. HERMAN-JOHNSON

### THE THERAPEUTIC ACTION OF CALCIUM SALTS

SIR,—In the *JOURNAL* of October 29th (p. 777) there is an account of the therapeutic action of calcium, from which one gathers that those who had studied the subject have very little opinion of its merits as a therapeutic agent. From my own experience and that of others there would seem to be something very far wrong with the methods used. I believe that such substances as calcium lactate may be very useful in such diseases as tuberculosis. I do not, however, wish to enter into this, but to refer to the action of calcium in the colloidal state, the particular substance I have used is Crookes's collosol calcium, which I have given extensively hypodermically and also by the oral route. The amount of calcium used is often very minute, as the strength is 1 in 2,000, and a dose of as little as 0.1 ccm may be sufficient to produce effects. It would seem therefore, that quantitatively it cannot have much effect.

The extraordinary rapidity with which this substance in some instances acts would seem to put it outside the class of ordinary therapeutic agents. I have known an empyema which had been discharging for weeks, the child rapidly getting worse, held up in a day or two and the patient recover in about a week from the administration of one teaspoonful of calcium (collosol) by the mouth at night. Ischio-rectal abscesses often of long duration will sometimes heal soundly in a week. In the case of the child quoted this effect could not be due to suggestion. Tuberculous glands may disappear rapidly. I am not wishing it to be inferred that these favourable results occur in every case, but they do occur in some cases. Last year I was consulted by a young man who was suffering so severely from his fever that he was unable to go to work. I ordered him one teaspoonful of collosol calcium by the mouth at night, and in a few days he was quite well, he took a little of the calcium this year, and was untoubled. This year I was consulted by a lady, aged 26, who since 1921 had been very much troubled with her fever, commencing in April and lasting till September, often being unable to go out, and her life a complete burden. I ordered her one teaspoonful of collosol calcium at night, she took this for six weeks and was no more troubled, even if she went into hayfever, she told me that this was the first summer she had been able to enjoy for years. I do not offer any explanation of the action of this substance, but that it does act I have no doubt—I am, etc.,

### CURE OF VARICOSE VEINS BY PUNCTURE

SIR,—Much has been written of late on the treatment of varicose veins by injection, and different formulae are recommended. I have followed the literature with interest, but have not yet made use of the method.

To-day I have had an experience which has surprised me and may be of interest. Two months ago a lady was recommended by a specialist to have a series of intramuscular injections of her own blood (5 ccm), and she came into my hands. Her limbs were adipose, and there seemed no chance of finding the veins at the elbow without dissection.

She had a group of varicose veins in the left leg below the knee, and blood was drawn from the vein on six occasions. Six weeks later she wrote that she had had a slight recurrence of her skin trouble—much less severe than in her previous attack. She thought the treatment had done good—might she have a second series. On visiting her I searched in vain for her varicose veins. They had disappeared—I am, etc.

#### QUININE BIHYDROCHLORIDE IN OBSTETRICS

Sir,—I can corroborate what Dr. Steel says (November 5th p. 827) about the value of quinine bihydrochloride in the treatment of puerperal sepsis. When practising in the East I saw many such cases (which had been attended by native nurses) and I never failed to effect a cure after the second injection. My first case was in the jungle many miles away from civilization—a multipara who had been confined four days previously. She had a temperature of 106° in the axilla, pain in the head and abdomen, and a foul discharge. I gave her an injection of 10 grains of quinine bihydrochloride. When I saw her early next morning the temperature was 99° and she had expelled a large mass of membrane. I gave her another injection that night and she made an uneventful recovery.

Since coming home I have seen three similar cases, adopted the same treatment and had equally good results. I always carry a supply of ampoules (P. D. & Co.) in my midwifery bag.—I am, etc.

BIRMINGHAM, NOV 11th

PROF. P. I. TON

#### JOHN OF CADDISDEN

Sir,—One hesitates at any time to intrude upon the expressed opinions of an illustrious and especially this, when the subject of it is a scholarly emanation of the profession like the late Dr. H. P. Cholmeley, but there is one untoward sentence in the excellent appreciation published in your issue of November 12th (p. 802)—untoward both in substance and in setting, for even if it were true there is no justification for association with the work or opinions of Dr. Cholmeley, and it is this: "the suggestion has been made that he [John of Caddisden] was perhaps the original of Chaucer's 'Doctor of Physic' in the Prologue to the *C Canterbury Tales*."

There is no suggestion of this in any chapter of Dr. Cholmeley's book *John of Caddisden and the History of Medicine*; indeed there is one reference which might be construed in quite a contrary direction. On page 71 he points out that, although the *Isis* is full of the beliefs and false pathology of the time, Caddisden makes scarcely any mention of "biological matters." In this he differs from his notable contemporary, John of Burgundy, who in his treatise *De Trinitate* lays it down as a necessity that those who presume to treat the plague should be well grounded in a knowledge of the stars. Chaucer's description is

With ther was a Doctor of Physic  
In al the world he was ther noon him lyk  
To speke of phisik and of surgerye  
For he was well grounded in a trewome

A few lines later, after referring to his doctor's knowledge of Esculapius, Apocryphus, and Cullen, he speaks of the works of Bernard (of Cordoba), Galien (Galenus), and Caddisden as forming part of his equipment. Chaucer had travelled far and read widely, and the "Doctor" is probably a composite picture; it is certainly more flattering to the medical profession than most medieval accounts are.—I am, etc.

VICTORIA INFIRMARY, CLIFTON, NOV 15th

J. A. M. CAMERON

\* We did not imply that the suggestion was made by Dr. Cholmeley. Sir Norman Moore in his article on John of Caddisden in the *Dictionary of National Biography* wrote: "His disposition, his peculiarities, and his reading

are so precisely those of the 'Doctor of Physic' in Chaucer's Prologue that it seems possible that Caddisden is the contemporary from whom Chaucer drew this character."

#### LUNACY LEGISLATION

Sir,—At the discussion at the Representative Meeting upon the report of the Royal Commission I pointed out that legislation might be introduced before the next Annual Meeting.

The Lord Chancellor at Northampton told us that the Cabinet was considering the report. The Minister of Health has said that the matter is urgent and the Chairman of the Board of Control has spoken in similar terms. In the circumstances I would urge that the British Medical Association should formulate its policy forthwith and that such policy should be supported by all members of the Association.

It will be impossible to construct a scheme which would meet the wishes of every individual but the present is a golden opportunity for improving the position of medical men in dealing with mental disease.—I am, etc.

FRANKLIN, NOV 9th

H. G. L. HAYNES

The importance and urgency of the matter is fully set out in the headquarters of the Association. The Lunacy Law Committee is meeting this day (Friday, November 18th) and may be expected to place its views before the meeting of the Council to be held on December 14th. The Council is acting on the assumption that early legislation is possible or not probable.

#### REFRACTION HOSPITAL

Sir,—My attention has just been drawn to a letter in the issue of October 29th signed 'A Bishop Hymn' in which reference is made to the 'London Refraction Hospital' in which it is stated:

The so-called hospital is no more than a meeting place where opticians collect some few patients, examine their eyes according to their capacity, and in trust their neophytes in their method.

The writer is evidently in complete ignorance of the facts. The number of patients attending the Refraction Hospital runs into some thousands per annum, less than a third of whom are sent by opticians. The opticians upon the staff in addition to their usual training in refraction have had the privilege of personal instruction in the detection of disease by ophthalmic surgeons.

The writer also states that the London Refraction Hospital would seem to be an attempt to combat the findings of the report of the Departmental Committee on the cause and prevention of blindness. The hospital building was purchased and the organization arranged some time before the report was published and before its contents could be known.

With regard to the word hospital the *British Medical Dictionary* defines it as a building for the benefit of any class of persons requiring public help.—I am, etc.

The Refraction Hospital  
London S.E.1, Nov 11

FRANK C. GREGG  
Lancaster

\* We have referred the letter to Mr. Bishop Hymn who writes: "Mr. Gregg is perhaps finding support for the comprehensive meaning that he wishes to attach to the term 'hospital' in the fact that there is to be found in one part of London a 'dolls' hospital' and in another a hospital for umbrellas. Whatever remote definition may be extracted from a particular dictionary it will hardly be contested that in common speech hospital means an organization where medical advice is to be obtained. When therefore Mr. Gregg's friends and their constituents to the hospital can here be any doubt that the great majority of persons so directed there are going to an institution staffed by qualified medical practitioners."

The suggestion that opticians' detritus of anatomical, physiological and pathological training can be made competent to examine disease in such a fashion as to extend the possibility of disease is of course absurd, and

still more absurd is the proposition that persons so "instructed" are efficient guides to succeeding generations of their junior colleagues. As Mr Gregg claims that his institution provides "public" help, it would be interesting to see the annual report and balance sheet, together with the names of the managers and supporters of the institution, so should thus learn the exact area from which this "public" support is supplied and the quality of the independent committee which governs the whole organization.

#### "THE HISTORICAL ASPECTS OF QUACKERY"

SIR,—Dr Kenelm Reid wishes me to say that no properly qualified doctor can legitimately be called a quack, whatever the nature of his belief. Sir James Barr, however, has recently (October 15th, p 704) expressed the opinion that "it would seem to me that in this country there are more qualified than unqualified quacks."

I suggest that Dr Kenelm Reid should settle this question with his friend Sir James Barr instead of demanding my opinion—I am, etc.,

Edinburgh, Nov 12th

\*\* This correspondence seems to have reached a stage at which it cannot profitably be continued

#### THERAPEUTIC ABORTION

SIR,—Dr Binno Dunlop has kindly defined the term "therapeutic abortion" as "abortion performed by a medical practitioner on purely medical—that is, pathological—grounds," although he does not outline these medical grounds nor describe the pathological investigations carried out. He further states that "abortion obviously protects family life" where it preserves the health or life of the mother of a family" (whether he intends to exclude the primiparous woman I do not know). This is dangerous doctrine. Will he show us before he performs an abortion that he will, with certainty, preserve the health or life of the patient? Again, if he be logical in his belief, may I not ask him to kill off some of the very numerous old people whose inconsiderate demands for attention from their married daughters do, I assure him, definitely damage the health of these mothers of families? After all, they are finished with their life's work, whilst the infants of whom he recommends the slaughter have not yet started theirs, and are much greater assets to the State.

If abortions are to be procured on the grounds that the health or life of mothers of families is endangered, then abortion should terminate every case of pregnancy, for pregnancy is never quite safe, 3,000 women were killed by pregnancy last year. Dr Dunlop excludes from the term "illegal abortion" cases of pregnancy following rape. These are admittedly hard cases, but "hard cases make bad law," and another platitude asserts that "two wrongs cannot make a right." May I suggest to Dr Dunlop that he may not exclude any intentionally produced abortion from the term "illegal abortion"? There is in this country no such thing as a legal abortion, as some in our profession may find out one day to their cost.

Seriously, Sir, some of us are greatly concerned at the number of abortions performed at the present day, and suspect that they are more easily obtained by the rich than by the poor. A case mentioned last year in the JOURNAL was that of a barrister's wife who "did not want a baby." If women marry they assume certain responsibilities, and it is not for the medical profession to enable them to shuffle out of these responsibilities.

We general practitioners who do not perform abortions see Nature produce living healthy babies in all kinds of apparently impossible circumstances. I have seen a woman with aortic heart failure at the fourth month go to term and produce a healthy child. I have seen grossly tuberculous women produce healthy babies and recover. We wish to see less interference with Nature. Nature can well look after herself, and, working unhindered, will produce healthy babies to carry on the race. There is no need to replace the term "maddlesome midwifery" with that of "maddlesome abortion"—I am, etc.,

London, N W 5 Nov 11th

P P DALTON

#### HOSPITAL POLICY

SIR,—It is high time the medical profession tackled the question of hospital policy in earnest. Why are hospital staffs so keen on the voluntary principle, and why will they not carry out the declared policy of the British Medical Association? Is not the profession ashamed of the methods which have been used for raising funds for voluntary hospitals? Would not it be more dignified to accept State aid on agreed terms? Cannot the profession see that the hospital clubs will eventually lead to the same position, as did the old friendly society and other kind of clubs? What is going to be the effect of all the clinics and the hospital out-patient departments upon the general practitioner? To my mind the last question is the most important of all—I am, etc.,

Southend-on-Sea Nov 14th

FERDINAND REES, M D

#### ASSISTED EDUCATION OF DENTISTS

SIR,—From time to time, in my capacity as Registrar of the General Medical Council, I am asked whether I know of any fund from which the sons or dependents of medical men can receive financial assistance to enter the medical profession, and my reply has to be that some of the medical schools have scholarships for this purpose, but, apart from this, I do not know of any fund from which they can be assisted.

With regard to dentistry, however, the position is different. Unless the entry of students to the dental profession is increased, it is not improbable that in process of time there may be a shortage of dentists to attend to the needs of the public. In suitable cases, therefore, in which the requirements of the General Medical Council for the registration of students have been satisfied, the board is prepared to give financial assistance, by means of bursaries, to pay the cost of fees and instruments, and in some cases maintenance is given in addition.

So far as is known, there is scarcely any other great profession for the entrance of which such facilities are provided. As it is possible that medical practitioners may know of cases in which young men, in every way suitable for entering the profession of dentistry, are debarred from so doing by lack of means, it is desirable that the assistance offered by the Dental Board should be made known.

Further information will gladly be sent on application to this office. All letters should be addressed to "The Registrar of the Dental Board," 44, Hallam Street, W 1—1 am, etc.,

November 10th

NORMAN C KING

#### Obituary.

JOHN SINGLETON DARLING, M D, M Ch,  
Late President, North of Ireland Branch, British Medical Association

WE greatly regret to record the death, on November 8th, of Dr J Singleton Darling, at his residence in Lurgan, Anagh, at the age of 71. Dr Darling received his medical education at Trinity College, Dublin. In 1879 he graduated M B Dublin, and obtained the Diploma L M, R U I, in the following year he became B Ch, and in 1909 proceeded M D, M Ch. In the last year of his studentship he obtained a travelling scholarship and studied in Vienna. After practising for a short time in the West of Ireland he went to Lurgan in 1883, and was appointed medical officer of the Lurgan workhouse infirmary seven years later. As the result of his work and inspiration the infirmary came to be regarded as a valuable school of surgery, and Dr Darling became renowned throughout Ulster as a skilful operating surgeon. After the war the hospital was officially recognized by the Government as a centre for the treatment of ex-soldiers.

Throughout his medical career Dr Darling did all in his power to further the interests of the British Medical Association. He was a member of the North of Ireland Branch Council from 1897 to 1899, vice-president in 1900, and president in the following year. He was honorary treasurer of the Ulster Branch and a member of the Branch Council from 1903 to 1927, and during the same period honorary secretary of the Portadown and West Down Division. He

represented the Branch on the Council of the Association without a break from 1914 to 1927. Dr Darling was a member of the Irish Committee from 1909 to 1911, and from 1923 to 1927, of the Finance and Executive Sub-committee of that committee from 1923 to 1924, he was a member also of the Insurance Acts Committee from 1920 to 1922. At the Annual Meeting of the Association in Belfast in 1909 he was vice-president of the Section of Obstetrics and Gynaecology. He had also held office as president of the Ulster Medical Society.

In addition to his deservedly high standing in the medical profession Dr Darling won the respect and affection of all who came in close contact with him. He will be sadly missed by his patients and the inhabitants of Limerick and his loss will be deeply felt by his colleagues in the medical profession throughout the North of Ireland and on the Council of the British Medical Association. He is twice married.

Dr ALFRED COX (Medical Secretary of the British Medical Association) writes: With Darling I grew up one of my oldest friends in the Association and one who for many years embodied the nobility and influence of the Association in Ireland as few other men did. To Darling it was that we naturally turned for information about what was going on in Ulster. He was the man who was just as naturally asked to do anything we wanted doing in Ulster and we were always certain that he would not fail us. He was a splendid influence in promoting medical unity and he did as much as any man to prove that there was no line of demarcation in Ireland between members of the medical profession whatever the political situation might be. His genial disposition and obvious sincerity made him a general favourite in the Council and the Representative Meeting. Members of such bodies will join with the colleagues in Ireland in mourning the loss of a good man.

# JONATHAN DALGLISH M.R.C.S. (L.S.A.)

Newcastle-on-Tyne

By the death on November 9th of Dr Jonathan Dalglish Newcastle-on-Tyne lost her oldest medical practitioner. He was born in North Shields on February 2nd 1829 and although he had entered all his professional commitments there are still members of many families in the city to whom he had rendered kindly services and by whom his memory is cherished. A student of the Newcastle College of Medicine he completed his medical curriculum in London. Returning to the northern metropolis he became assistant to Dr Raine a well known and popular medical practitioner in his day who was surgeon to the North Eastern Railway Company. Dr Dalglish commenced practice on his own account in Westgate Road then a residential street he gradually built up a large connexion and subsequently removed to West Parade where he lived until 1901. During the years he led an extremely active life. He was one of the first disappearing type of the 'good old family doctor' guide and friend as well as medical adviser. On January 1st 1864 Dr Dalglish was appointed a district medical officer under the guardians a position which he held until June 24th 1901 when he retired with a pension after thirty-seven years of Poor Law service. He was one of the first six medical men to become a public vaccinator for the city in 1872 a year after the second Public Vaccination Act became law. The first Act was passed in 1867 and although there is no record of the fact it is more than likely in the intervening period he discharged such duties as the Act required.

In the latter years of the past century he conducted a mission in Surgeons' Hall on Sunday evenings. He retired temporarily to Harrogate where five months afterwards his wife died and he returned to Newcastle. He established a medical mission in Shieldfield, one of the crowded working class districts which he carried on single-handed for eleven years. While warmly interested in mission work he was not only a keen Biblical student and an example of the application of the tenets of the New Testament to daily life, but equally a close student of medicine even in

his declining years. He bought and read the newest editions of standard books on medicine, so that his library was kept up to date until the last few years when he began to suffer from cataract. This was a great blow, for he loved books. Unfortunately the blow was further embittered by great loss of hearing. The deprivations he bore with fortitude and patience, an example to all who came into contact with him and an illustration of the triumph of the faith which sustained him. A friend to all and a friend of none his funeral, in Old Lamond Cemetery on November 12th where he was buried beside the remains of his wife was attended by the civic dignitaries and members of the public bodies of the city and a few of his old medical friends and patients.

One of his sons, an ophthalmic surgeon died in Sunderland in 1910. Of the four sons who survive him Dr John Dalglish is a medical practitioner in Sutton Surrey one Mr Robert Stanley Dalglish had just closed his career of office as a much appreciated sheriff of Newcastle on the day his father died, one son lives in York here and the other in New Zealand. Three married daughters survive him.

# SIR PETER O'CONNELL M.D., M.Ch.

Consulting Surgeon Mater Infirmorum Hospital Belfast

There was universal regret when it became known in Belfast that Sir Peter R. O'Connell had passed away on September 24th at Marseilles where he had gone on holiday. Peter O'Connell who was born in Co. Caran, went to Belfast when a young man in 1853 after graduating M.D., M.Ch. R.C.L. and post-graduate study in Dublin London and the Continent. His reputation had preceded him, and the nucleus of the present Mater Infirmorum Hospital was founded by him in association with a few colleagues. There he laboured hard and as a result the present hospital was opened in 1900 with 200 beds. He was then appointed chief surgeon. In this sphere he had ample scope for his work and soon his operative skill and highly valued opinion brought him patients from all over Ulster. Though busily engaged in practice he found time for writing on various subjects and became interested in societies for the improvement of the people. He was prominent in a peak, and was elected as chairman of the city of Belfast. In the corporation he took a keen interest in public health technical and education matters. He was elected High Sheriff of the city in 1907 by whom he differed from him both in religion and politics but who recognized his great ability and he was elected a Knight Bachelor in 1903. He was also a deputy lieutenant for the city. He was a member of the commission which inquired into university education in Ireland and he might almost the establishment of the National and Queen's University. He was appointed a censor of the latter and acted as lecturer and examiner in surgery. He was elected president of the Ulster Medical Society in 1910-11. He retired some half-dozen years ago and went to live in the neighbourhood of Dublin. A colleague writes: In the Mater we shall miss his ready presence and his calm advice his sallies of wit and his profound but his name and fame are well known in its history. He has laboured for nearly forty years and future generations will gain a deep debt to his memory. To his widow Lady O'Connell daughter of Edward Hugh J.P. we tender our most sincere sympathy and pray that time may soothe the great loss which has befallen him.

The following well known foreign medical men and recently died Professor Max von GUERBER for many years director of the Institute of Hygiene at Munich and President of the Bavarian Academy of Sciences and Dr Otto POHN formerly professor of medicine and bacteriology at Zurich and 75 Dr JESSE LOUIS PROCTOR formerly professor of physiology at Cornell University and 77 Dr Max RICHNER one of the oldest and most distinguished rhinolaryngologists and Dr KURT OBER on former professor of the surgery of children at Jena and a Dr PHILIPPE of Medicine and surgeon to the Hôpital des Enfants Malades, Paris.

## UNIVERSITY OF CAMBRIDGE

At a congregation held on November 12th the following medical degrees were conferred

M B B Chm.—J L Warner  
M B—W H Craib

## UNIVERSITY OF BIRMINGHAM

The following prize medals awarded for the past session were distributed at the meeting of the faculty of Medicine, held on November 11th, by the Vice Chancellor and Principal (Dr C Grant Robertson) Arthur Farnell Memorial Medal (Gold Medal awarded on Clinical Medicine, Final M B, Ch B Examination), Marjorie V Martin Sampson Gamace Memorial Medal for Surgery (Gold Medal awarded at Final M B, Ch B Examination) K P Fooks Prizes awarded by the University Clinical Board Senior Medical Prize (Gold Medal), Frances M Stookdale, Senior Surgical Prize (Gold Medal), V Goldman, Midwifery Prize (Gold Medal), R Anderson, Junior Medical Prize (Silver Medal), J W Notley, Junior Surgical Prize (Silver Medal), Beatrice M Willmott

## UNIVERSITY OF GLASGOW

At the congregation on November 12th the degrees of M B, Ch B were conferred upon Eric Dow, and that of B Sc in Pure Science on Martha Cleland, M B

## ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

The following officers have been elected for the ensuing year President Dr G H Edington Pastor Dr John K Burgess Honorary Treasurer Mr J H MacDonald Honorary Librarian Dr E H L Oliphant Representative on the General Medical Council Dr James A Adams Counsellors The above named office bearers *ex officio*, together with Dr John Henderson Dr H L G Leask, Mr R Barclay Ness Dr T K Monte Dr W G Dun, Mr J Iorhos Webster Dr J M Munro Kerr, Mr Thomas Kay, Mr John Patrick and Mr R M Buchanan S A M Sepher (Hong Kong) has been admitted (after examination) as a Fellow of Faculty

At the general meeting of the Faculty on November 7th Dr G H Edington the new president, was invested with a badge of office, presented by his predecessor, Mr R M Buchanan

## ROYAL COLLEGE OF SURGEONS OF ENGLAND

An ordinary Council meeting was held on November 10th, when the President, Sir Berkeley Moynihan, was in the chair

## Diplomas

Diplomas of Membership were granted to 178 candidates

## Learner

Mr Herbert Tilley was appointed to examine for the Diploma in Laryngology and Otology in December, in place of Mr A H Cheate, resigned

## International Congress of Military Medicine and Pharmacy

Sh Anthony Bowlby was nominated to serve on the organizing committee of the fifth International Congress of Military Medicine and Pharmacy, to be held in London from May 6th to 11th, 1929

## Members and Direct Representation

In reference to the resolution carried at the last annual meeting of Fellows and Members, the following resolution was unanimously adopted

"That in view of the result of the recent postal vote of the Fellows the Council is not prepared to take steps at the present time for altering the constitution of the College so as to give Members of the College direct representation on the Council"

## Retirement of Mr Hallett

The following resolution was passed

"On the occasion of the retirement of Mr Frederic G Hallett from the offices of Secretary to the Joint Examining Board and Director of Examinations in the Royal College of Surgeons, the Council desire to place on record their high appreciation of his services and the very warm regard which they entertain for him personally. Mr Hallett's powers of organization, his long experience in all matters relating to examinations, and his exceptional knowledge of regulations for medical education in this and other countries have been of great advantage to the College, and have given his services a special value and caused them to be held in the highest regard. The Council are fully conscious of the ability and zeal with which Mr Hallett has carried out his duties during the long period of fifty years, and they trust that health and happiness may enable him to enjoy in his retirement the rest which he has earned so well. His unfailing courtesy and readiness to help will not be forgotten by those who have had the pleasure of being associated with him in the control and management of the affairs of the College and the Council assure him that he carries with him their best wishes for his welfare in years to come"

## Medico-Legal.

## BRITISH MEDICAL ASSOCIATION v ALBERT PARTON AND PARTONS LIMITED

## MOTION FOR INFRINGEMENT OF COPYRIGHT PERPETUAL INJUNCTION GRANTED

In the High Court of Justice, Chancery Division, before Mr Justice Romer, on November 16th, the British Medical Association applied for an injunction to restrain Albert Parton and Partons Limited, of New Cross Road, London, from publishing or distributing a pamphlet which, they alleged, infringed their copyright

Mr C A Bennett, K C, and Mr H C Dickens were counsel for the British Medical Association, instructed by Messrs Hampson. Mr Parton conducted his own case

Mr Bennett said that the copyright which British Medical Association, declared to be two of their publications, *Secret Remedies* and *More Secret Remedies*, and the infringement was in a pamphlet published by the defendants called *The Greatest Exposure of Modern Times Patent Medicines* (so called), *What they cost and what they contain*, as exposed by the British Medical Association. When the case came previously before the court his lordship suggested to Mr Parton that he should consult solicitors. He had done so, and at the beginning of last week the British Medical Association received a letter from the solicitors stating that they had gone into this matter with the defendants. Mr Parton, as was to be gathered from his previous statement in court, was contending that under Section 10 of the Copyright Act, 1911, proceedings for infringement of copyright had to be taken within three years of infringement. He had been advised, however, that his offence was a continuing one, and in these circumstances defendant had expressed his willingness to attend at the adjourned hearing of the motion, that day, and to raise no further objection. He was also prepared, in order to avoid expense, to agree that the motion should be considered as the trial of the action. The British Medical Association was quite willing to put an end to the matter on these terms. There were, however, two defendants, Mr Parton and a limited company, of which he was the principal director and a substantial holder of the shares, and neither he nor the company had as yet "entered an appearance"

His lordship said that all he could do was to grant an injunction until the trial. In the meantime, the two defendants agreeing that motion could be treated as the trial, and the injunction made perpetual during copyright. He understood that the Association did not ask for damages

Counsel said that his clients did not ask for damages, but they did ask that defendants should deliver up on oath all copies of the pamphlet in their possession or power, and all printed sheets and type used for their production. He thought he was entitled to ask for that, also the costs of the motion

His lordship agreed, and, addressing Mr Parton, said that no doubt he had heard what counsel had said. Defendants had not what was called "entered an appearance." No doubt Mr Parton for himself, if not for his company, could enter an appearance that day by attending before the learned registrar, giving his consent to the terms mentioned, and then no further costs would be incurred

Mr Parton said that he would do this

Counsel said that there was one other matter. This was only a motion for infringement of copyright, but defendant had been addressing meetings at which he had tried to sell the remedies in circumstances which suggested that he was acting under the auspices of the British Medical Association. Counsel only desired to say that if he continued to do this it might be necessary to take other proceedings to stop him. The British Medical Association had no connexion with him at all

Mr Parton said that on his new flag, which he had used during the last three months, he had made no mention of the British Medical Association

His lordship said that Mr Parton would be well advised to cease to make any reference to the British Medical Association, and especially not to suggest that he had any connexion with them. His lordship then, subject to Mr Parton and his company "entering an appearance," granted the perpetual injunction asked for, with delivery up of copies of the pamphlet, and costs against the defendants

## A CONSULTANT'S FEE

At the West London County Court, on November 14th, before His Honour Deputy Judge Ralph Thomas, Sir Thomas Horder, Bt, M D, was sued by Mr Robert Sidney Provis, described as a "consultant in blood diseases," of West Kensington, for the return of five guineas, a consultation fee. Sir Thomas Horder

was presented by Mr Michael Rowe, barrister Mr Provis conducted his own case

Mr Provis testified that between 1918 and 1923 three of his brothers died from pernicious anaemia and he himself towards the end of that period contracted the disease. He consulted many medical men in this country and abroad and all of them gave him the same dreadful poisons to imbibe. Eventually he consulted Sir Thomas Horder, who asked him if he had had any injections and said that he would prescribe six injections, the nature of which he was not told. He asked Sir Thomas whether this would cure him and Sir Thomas replied "No but it will help you. The prescription was sent to Dr Spurgin of Bramhall together with a letter which Dr Spurgin said he had made and by Dr Spurgin he was told that the six injections were of salvarsan and that they could not be put into his body because he had no veins. He then went to Dr Arnold Renham of Manchester who gave him the first injection which paid off his harm and cured him. On the second occasion Dr Spurgin missed the vein with the result that the water was offered intravenously and it was only my own knowledge of the blood stream that enabled me to prevent that poison reaching my trunk. (At this point the judge remarked that he would hear better if the plaintiff did not address himself to the jury.) Continuing Mr Provis said that since that time he had himself acted in practice as a non-orthodox healer.

His Honour: How does that affect your case?  
Plaintiff: It has shown me that Sir Thomas Horder did not and I stand in my case. It was a very bad case and wrong treatment. I cut it out and I have cured others since. I maintain that Sir Thomas Horder took a course from me for a prescription which was worth a lot but endangered my life. I ask for the return of the five guineas. If a trial is to be made I am sure worth of the best I should have my return in court. I do not ask for damages.

Cross-examined the plaintiff was asked if salvarsan was not a remedy very commonly given to which he replied "Very common unfortunately. On another question whether in the existing state of medical science it was not the best remedy the judge interjected "Is he in a position to know that?" He is an "orthodox healer" which means an unqualified practitioner. Several letters which the plaintiff had written to Sir Thomas Horder were put in. One of them contained a cutting from the *Health Express* advertising Mr Provis and the remark was written (thereby by Mr Provis in what he admitted to be a different hand) coming from that named in the other letters. This man [meaning Plaintiff] is no fool.

The judge called attention to the letter heading "R S Provis Director of Natural Therapeutics" and to his assumption of the title "Doc or" and asked Mr Provis who gave him his degree.

Plaintiff: I claim the degree because there is nobody in this country who can see my knowledge.

His Honour: You are not entitled to call yourself a doctor?

Plaintiff: Doctor only means teacher.

His Honour: You have no degree.

Plaintiff: No degree recognized by the Government at the moment.

His Honour: Have you a degree which is not recognized? Who granted you your degree?

Plaintiff: Almighty God who endowed me with the most marvellous power of healing and preaching.

Extracts from other letters written by the plaintiff to Sir Thomas Horder were read. One of them headed "White Loas" contained the sentence "Large millers of white flour are not without interest in your lies. Another saw. It is my intention to let the public know you are a liar and another. I am not afraid of the old B.M.A." The plaintiff also stated that he had discovered the cause of cancer and consumption and that he had himself treated lots of cases of cancer which have gone well.

His Honour: What do you mean by that—that the patient died? Plaintiff: Oh no the patients recovered. It was the cancer that was cured.

He added on further cross-examination that it was not until he became acquainted with the Spallinger controversy that he realized that the treatment prescribed by Sir Thomas Horder was really blood poisoning. He knew that he had had blood poisoning in consequence of the treatment but he was not aware until that controversy that blood poisoning was part of the game. He was anxious to challenge Sir Thomas Horder to debate on the "white loaf" and other questions and was ready to engage a hall but he had not seized the present occasion for publicity. He wanted only the return of his fee.

Comment for Sir Thomas Horder submitted that there was no cause of action. There could be no question of negligence in administration so far as Sir Thomas Horder was concerned. Moreover plaintiff had admitted that Sir Thomas Horder had not promised to cure him. He could hardly deny that he was given a remedy commonly used by medical practitioners nor that he received the best advice available when he consulted Sir Thomas Horder.

Plaintiff in a final speech on his own behalf said that Sir Thomas Horder did not get his money until he had cured the plaintiff (that what he was prescribing would help him). He maintained that if one went to a high authority in the medical profession one expected something better than from a "ten and a penny practitioner."

#### Judgement for Sir Thomas Horder

His Honour in giving judgement said that plaintiff was not suffering that the fee was excessive but only that the result of the treatment advised by Sir Thomas Horder was that he got blood poisoning. His Honour agreed with the submission made by counsel for the defendant that there was no warranty or guarantee in the case in any way. Plaintiff asked Sir Thomas Horder for his advice. Sir Thomas Horder gave his advice and it was not

suggested that there was anything improper about that advice. Any improper administration of the medicine such as plaintiff alleged could not of course be brought against Sir Thomas Horder. Moreover the plaintiff himself said that he was not seeking to recover damages for anything that Sir Thomas Horder had done. The letters which had been put in and plaintiff's attitude in the witness box made one suspect that this action was not genuinely started for the purpose of recovering a fee paid to Sir Thomas Horder. He found for the defendant with costs and refused leave to appeal.

### Medical Notes in Parliament

THE Parliamentary Medical Committee is to meet on November 24th to discuss the prospects of the Nursing Homes Bill and Mental Deficiency Bill and also Dr Little's bill regarding medical confidences. A letter from him on this subject is published at page 957. The Parliamentary Medical Committee has not been consulted in the preparation of the bill. A deputation of medical members of Parliament to the Minister of Health on the same subject had previously been suggested though no arrangements had been made for it. The text of the bill is as follows:

BE it enacted by the King's Most Excellent Majesty by and with the advice and consent of the Lord Spiritual and Temporal and Commons in this present Parliament assembled and by the authority of the same as follows—

1 Any information obtained by a duly registered medical practitioner in regard to any person treated for venereal disease under a scheme approved in pursuance of Article II (2) of the Public Health (Venereal Diseases) Regulations 1916 S.P.C.O. 1916 (No. 467) shall be regarded as confidential and shall be privileged from disclosure under the court of law.

Provided that the information obtained shall have been obtained for the purpose of a cure or a sitting in a cure of a person so treated.

And provided also that this privilege shall not extend to any communication made with the object of committing or aiding in committing any fraud or crime.

2 For the purpose of this Act duly registered medical practitioner shall mean a person whose name is on the *Medical Register*.

3 This Act shall be called the Medical Practitioners' Communication Privilege Act 1927.

The Government which controls all the time of the House till the end of the session has not promised facilities for discussion.

#### Landlord and Tenant Bill Goodwill

The Landlord and Tenant Bill introduced by the Government to provide a remedy for hardships to business tenants under leases granted after its passage into law was considered by the House of Commons on report on November 15th Mr Wellock moved to extend to premises occupied for professional purposes the provision that compensation could be claimed for goodwill. He said that doctors had come together in particular areas in almost every town and it was possible for a landlord to turn out one and bring in another thus gaining the advantage of any improvement which had been made. Sir William Jovonovich said there was a difference between the goodwill of a doctor and the goodwill of an ordinary tradesman. The Government had agreed while the bill was in Committee that the professional man should have compensation for improvements. It would be better to wait a few years to see how the Act ran before considering its extension to other classes of occupier. The Committee on the bill had unanimously accepted the compromise that professional men should be entitled to compensation for improvements but not for goodwill. Mr Dalton said that the doctor dentist or other person given a choice would prefer compensation for goodwill to compensation for improvements which he agreed had to make. Sir Philip Pilditch said the Committee had agreed that the doctor or dentist should be given facilities for securing the goodwill of a business by putting up such a building as a garage. Mr Stephen remarked that a professional man who failed to put ten miles out could not expect his clients to follow him. Mr Wellock asked for guidance on clause 15 (3) which provided that in the case of premises used partly for professional or business and partly for other purposes the compensation for improvements and goodwill shall apply to improvements only and so far as the improvements are in relation to the trade or business. He inquired whether this subsection in the case of a doctor in a well known district would cover compensation in respect of that doctor's reputation. The Home Secretary said that it would. The amendment was then adopted by 165 to 53 and the report stage was completed.

National Insurance.—On November 16th Mr Chamberlain told Colonel Aspin that approved societies had no power under the National Insurance Act to establish dental clinics but a few could have been established by bodies indirectly connected with approved societies. He hoped soon to receive a report on the provision of dental treatment in clinics from the special committee representing approved societies and dentists to which he had referred the question. Answering Mr Hard's question Mr Chamberlain said that during August the average cost of a prescription under the National Health Insurance Act was in London £1.6d. Birmingham 7.6d. Manchester 8.2d. and Liverpool 8.5d. The average cost per

prescription for medicine for insured persons in Glamorgan during August last—the latest month for which figures were available—was 13,414. The Minister of Health has received from the Glamorgan Insurance Committee a letter protesting against Wales being ignored in the composition of the Pharmaceutical Distribution Committee. The committee he stated was constituted on the same lines as the Medical Distribution Committee, which has never contained any separate representation of the Welsh Insurance Committees. The two committees are already sufficiently large, and the Minister sees no necessity to increase them.

**Extensions of Voluntary Hospitals.**—In an answer to Mr. T. Williams on November 13th Mr. Chamberlain again said that he could not recommend any grant from public funds towards the cost of extensions of voluntary hospitals. Since the Oswestry Commission reported a considerable number of new beds had been provided or were in course of provision.

**Smallpox.**—Sir Kingsley Wood on November 14th, informed Dr. Vernon Davis that the number of cases of smallpox notified in August, September, and October were 561, 505, and 795 respectively. The total number of notifications from January 2nd last to November 5th inclusive was 12,729. These figures were subject to revision. Sir I. Gilman also told Dr. Davis that the numbers of cases of smallpox notified in Scotland during August, September, and October 1927, were 5, 2, and nil respectively. The total number of cases of smallpox notified in Scotland from January 1st, 1927, to November 5th, 1927, was 166.

**Baths at Poor Law Institutions.**—Mr. Chamberlain on November 14th, said his attention had been drawn to the remarks of the coroner at an inquest at Hammer Smith regarding the death of a woman through drowning in a bath full of water at a hospital, she having taken a bath against instructions. He said the importance of having keys to all hot water taps in the bathrooms of Poor Law institutions had for many years been emphasized by the central authority. Such keys had now been fitted at this institution.

**Proposed Medical Mission to China.**—On November 14th Lord Winton informed Mr. T. Williams that a proposed medical mission to China had been discussed by the Indian Government because a grant of facilities for British subjects to serve as non-combatants with one or other of the contending factions in the civil war in China would have been considered as a departure by the Government from its attitude of strict impartiality. The Government had advised British subjects to withdraw from the interior of China in order to avoid embarrassing incidents and it could not allow a party of British subjects to proceed to parts of China where such incidents were most likely.

**Foot and Mouth Disease.**—Mr. Guinness replying on November 15th to Lord Apsley said that the departmental committee which reported on foot and mouth disease in 1922 and 1925 expressed the view that the virus might be introduced from abroad through two classes of channels: (a) uncontrollable such as the movement of birds and airborne infection and (b) controllable such as the movement of human beings, importation of animals, feeding stuffs, packing materials, trolleys and men. To prevent the introduction of disease through the controllable channels a number of Orders were in force such as that prohibiting the import of hay and straw from countries in which foot and mouth disease was prevalent and of fresh carcasses from the Continent. Other Orders were designed to prevent the spread of infection once it had occurred in this country.

**Medical Inspector of Mines and Quarries.**—On November 15th Colonel Lane Fox replying to Mr. J. W. S. said that Dr. S. W. Fisher had been appointed medical inspector of mines and quarries. Since his demobilization in 1919 Dr. Fisher had practised in a colliery district in South Wales, where he had obtained general experience of mining conditions and of the treatment of mining accidents and disease. He had taken special interest in silicosis and myasthenia in which he had carried out research work, and in bent hand, bent knee and bent elbow.

#### Votes in Brief

Mr. Chamberlain told Sir Nicholas Grattan Doyle on November 16th that he had no power to curtail the activities of birth control societies and similar agencies.

Mr. Chamberlain told Mr. Bromley on November 10th that he was communicating with the Lancashire County Council about the future use for tuberculous patients of the Limeside Sanatorium, Lancaster, in which three patients had lost their lives recently by the flooding of the institution. There was no suggestion that all reasonable precautions had not been taken.

In reply to a question Mr. Chamberlain said on November 10th, that he was advised there was no danger that tuberculosis could be communicated to man by the consumption of fish. He did not propose to have investigations made with a view to prohibiting such sales.

Major Dixon states that no general instructions have been issued that the treatment allowances of men suffering from tuberculosis in consequence of war service should be withdrawn. The circumstances of each patient are considered in consultation with the responsible medical officer. The special difficulties which had arisen over such cases in the Ilford district were being investigated. The Minister of Health had considered the resolution passed by the Plymouth Insurance Committee urging the Government to enable and require local authorities dealing with tuberculosis—or groups of them—to formulate schemes for village settlements where suitable ex sanatorium patients and their families could be housed and appropriate remunerative employment provided under medical supervision on the lines adopted at the Cambridgeshire tuberculosis colony at Pipeworth. There

were three village settlements in existence, and a fourth was under consideration. Fuller experience of the results in these cases must be awaited before attempting such widespread and costly developments as the question suggested.

In the year ended June 1927, 117,000,000 gallons of milk were brought into London by the four principal railway companies—an increase of 62 per cent since 1923. At least 5,000,000 gallons a year are also brought in by road.

The Government of Burma has decided not to reopen the opium registers for Burman customers without a clear mandate from those affected.

The Prime Minister, on November 14th, told Mr. Tooker that he was aware of the importance attached by governing bodies of institutions for mental defectives to the Mental Deficiency Bill 1927 being passed into law at the earliest possible moment. He could not, however, add anything at present to his statement of last week about the prospect of facilities being given for its passage this session.

## Medical News.

SIR BIRKBECK MAXIMIAN will deliver the Mitchell Binks Memorial Lecture for 1927 in the Medical School of the University of Liverpool on Thursday, November 24th, at 4.30 p.m. The subject of the lecture, which is open to members of the medical profession, is 'The gall bladder and its infections.'

The first International Conference on Light and Heat in Medicine and Surgery will be held at the Central Hall, Westminster, S.W., on December 13th to 16th. Among those who will read papers on various aspects of ultra violet therapy and hundred subjects will be Professor Leonard Hill, Professor I. M. Heilbron, Dr. T. Hermann Johnson, Dr. I. Howard Humphris, Dr. H. Stanley Banks, and Dr. L. P. Cumberbatch. Foreign representatives who will read papers will include Dr. Jean Seldman (Paris), Dr. L. G. Dufostel (Paris), and Dr. Franz (Vienna). Each paper will be followed by a discussion. Tickets should be made to 17, Catherine Street, W.C.1.

The annual reunion dinner of the British Serbian Units Branch of the British Legion and of all friends of Serbia will be held on Saturday, December 3rd, at 7.15, at the Victoria Mansions Restaurant, Victoria Street, Westminster. The president, the Rev. R. G. D. Laffan, will be in the chair. Tickets can be obtained from the honorary secretary, Miss Mair, 24, Molecombe Court, Dorset Square, N.W.1.

Mr. A. Edwards will deliver a lecture for the Fellowship of Medicine on practical surgical details at the Medical Society, 11, Chandos Street, on November 21st, at 5 p.m. On November 23rd, at 2.30 p.m., a special demonstration will be given at the Prince of Wales's General Hospital, Tottenham, N.15, on November 14th, at 2 p.m., Mr. Whitechurch Howell will give a surgical demonstration at the Queen's Hospital for Children, and on the same day, at 1 p.m., Mr. Whiting will give a demonstration at the Royal London Ophthalmic Hospital, City Road, E.C.1. The lecture and demonstrations are free to medical practitioners. From November 21st to December 17th there will be a daily series of lecture demonstrations, illustrated by cases, at the West End Hospital for Nervous Diseases, at 5 p.m. A week's post graduate course in diseases of the rectum will be held at St. Mark's Hospital from November 28th to December 3rd inclusive. Two afternoon courses begin on December 5th and continue for two weeks, one at the Infants Hospital, under the direction of Dr. Lucie Pritchard, will cover all phases of the study of infantile diseases, and the other will be held at the Hospital for Diseases of the Skin, Blackfriars. During January the following courses will be arranged in medicine, surgery, and the specialties at the Prince of Wales's General Hospital and associated hospitals, in epidemiology at the National Hospital for Diseases of the Heart, in diseases of children at the Children's Clinic, and in psychological medicine at the Bethlem Royal Hospital. Syllabuses, tickets, and specimen copies of the *Post Graduate Medical Journal*, may be obtained from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

A PRACTICAL course in the treatment of skin diseases and syphilis will be held at the Hospital St. Louis, Paris, from November 28th to December 20th, under the direction of Professor Jeansolme, assisted by Professor Schileau and the staff of the hospital. The fee is £250. Further information can be obtained from M. Buisson, Pavillon Bazin, Hospital St. Louis, Paris.

A POST GRADUATE course in neurology and psychiatry will be held in English, from January 2nd to February 28th 1928, in Vienna. Further information can be obtained from Dr. E. Spigler, I. Allostasio 3, Vienna I.

DR. G. ARBOUR SELPHENS has been appointed an alderman of Swansea.

PROFESSOR R B WILD who retired in September last from the Leech chair of water medicine and therapeutics in the University of Manchester was presented on November 11th with his portrait by Francis Dodd A.I.A., a set of Kilgiving's work, and an album of limnophone records of Beethoven's Symphony No. 3. The presentation was made by Professor G R Murray on behalf of Professor Wild's past and present colleagues in the Faculty of Medicine in appreciation of the valuable services he has rendered to the cause of medicine and education in Manchester. In accepting the gifts Professor Wild expressed a desire that the portrait should be given to the University, and the Vice-Chancellor gratefully accepted the offer.

The Minister of Health and the Minister of Agriculture and Fisheries have appointed a Joint Advisory Committee with Sir Horace Monroe K.C.B., as chairman to consider and report on the position with regard to the pollution of rivers and streams and on any legislative administrative or other measures which appear to them to be desirable for reducing such pollution. Among the members is Dr H M Lean Wilton, chief inspector of the River Board of the West Riding of Yorkshire. Communications may be addressed to Mr G C North V.C., one of the secretaries of the Committee at the Ministry of Health, Whitehall, S.W. 1.

A HOME OFFICE Order, which will come into force on December 1st requires that suitable washing facilities shall be provided in all factories and workshops in which sugar is used in the processes of icing, creaming, and filling biscuits and wafers. A weekly inspection is also ordered for the detection of early signs of dermatitis of the hands and forearms and in the event of any such susceptibility being detected arrangements must be made for the person to be transferred to work which will not expose him to contact with sugar.

An inquest was held on November 14th at Poplar on the body of Mr William Smart Harnett, aged 65 which was found in a dock last week. The medical evidence indicated that the body had apparently been in the water for ten or twelve days and that death was due to asphyxia from drowning. Mr Harnett will be remembered as the plaintiff in two prolonged lawsuits against medical men—Harnett v Bond and Adam and Harnett v Fisher—both of which were fully reported at each stage in these columns. He had been missing from his home for over a fortnight before his body was found. The coroner in his summing up recalled that Mr Harnett had been certified some time ago as insane, the fact that he was found, as the result of litigation not to be insane could have had very small bearing on his recent actions: there was evidence that for the past four years or so he had acted perfectly normally. The jury without retiring brought in a verdict of 'found drowned'.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

**ORIGINAL ARTICLES and LETTERS** forwarded for publication are understood to be offered to the **British Medical Journal** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the **British Medical Journal** must communicate with the Financial Secretary and Business Manager, **British Medical Association House, Tavistock Square, W.C.1** on receipt of proofs.

All communications with reference to **ADVERTISEMENTS** as well as orders for copies of the **Journal** should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the **British Medical Association** and the **British Medical Journal** are **MUSEUM 5957** and **5958** and **5959** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are **EDITOR** of the **British Medical Journal** **Antilogia Westcent London**.

**FINANCIAL SECRETARY AND BUSINESS MANAGER** (Advertisements etc.) **Articulata Westcent London**. **MEDICAL SECRETARY** **Medicera Westcent London**.

The address of the Irish Office of the **British Medical Association** is 16 South Frederick Street, Dublin (telegrams **Deccus Dublin** telephone 4731 Dublin) and of the Scottish Office 6 Drumhugh Gardens, Edinburgh (telegrams **Associate Edinburgh** telephone 24351 Edinburgh).

### QUERIES AND ANSWERS.

"I. A. wishes to hear of an institution where a patient could receive the latest treatment of locomotor ataxia. There are no mental symptoms. Payment to cover the cost of keep could be made."

### STOMACH COUGH

A CORRESPONDENT sends us the following note of his own case. The inquiry by M B Cantab in your issue of November 4th describes a condition which I have observed for some years though my case is not as a rule so acute. I is hard to understand a condition at once so acute and so quickly relieved but I suppose that for the individual at any rate there is a very small margin between the normal acid value of the gastric juice and an acidity which irritates the stomach wall. When the latter is established the patient is awakened by the discomfort and the pylorus contracts. Gulping of air which is involuntary but can be partly retrained by the will forms on all the stomach is sufficiently intended to provoke violent and painful contraction reflex coughing and ultimately vomiting. A very small amount of sodium bicarbonate taken on waking so lowers the acidity and diminishes the irritation that the previous reflexes, the contents of the stomach begin to move on and the passing of flatus hitherto inhibited takes place. The patient then the normal conditions of contraction pass down the bowels and resumed he goes to sleep almost at once and has no remembrance in the morning. The practical treatment then is a combination of two or three soda mint tablets immediately on waking and a cocaine lozenge (such as Glaxo) and keep a small amount of it slowly sucked. The latter probably stops the cough and greatly diminishes the risk of vomiting.

J B S writes: M B Cantab does not say how long I or how his cough first began. In those days I used to have coughs at undue exposure during the day brings a bill to be met for an attack of coughing in the morning. I am much perturbed thinking brings a sensation in the epigastrium of an almost soreness and attended by some faintness in the forenoon. I have arrived at the age when the legs easily get cold—this gives me a cough in the morning but no irritation in the throat. I had that gentle massage with gulping in the epigastrium and gentle pressure including the neck of some service. Distending to startle on as regards last meal.

### CATARACT AND ULTRA VIOLET LIGHT

A MEDICAL CORRESPONDENT asks whether there is any reason to suppose that treatment of cataract with ultra violet light is likely to benefit the condition.

We referred this question to Mr Bishop Harman who has been good enough to send the following reply. Ultra violet light is injurious to the eyes. The naked eye if it be formed on the macula will cause a scotoma or blind spot which may have permanent damage. Even when no actual lesion of the eyes the rays will set up severe conjunctivitis akin to the so-called blindness of the high Alps. The preliminary report of the committee on the Causes and Prevention of Blindness reported at the request of the Minister of Health (Dr Addison) on an outbreak of eye inflammation that had occurred in film studios. The attacks were due to the use of unfiltered or naked arc light rays. The mercury vapour lamp is milder in action but is capable of producing similar irritation if no screened. Users of ultra violet ray apparatus need to take special precautions by the use of suitable glasses (not merely tinted but opaque to the short rays) so as to protect their eyes from damage. It is obvious from these facts that treatment with rays will not benefit cataract. Indeed there is some evidence that liable to cause cataract. Cataract is common in India where excess of sunlight is found. It is true that food factors have some possible effect but since the earliest changes are commonly found in the lower half of the lens it is probable that this selection is the effect of light. When cataract is actually present—the lens then the lens is opaque—no form of treatment will alter the same operation. It is said that there is a cult of sun-worshipers in India who gaze at the sun for some time each day. One of these came to me as a patient recently. This Indian gentleman assured me that for one hour daily he gazed naked-eyed at the sun. On examination it was found that he had advanced cataract in each eye and his visual acuity was greatly reduced.

### COLD HAND

A M writes: I recommend W G who suffer from cold hands (Journal November 12th p 50) to try the following device which I made when I used a pedal motor cycle. I found to be the only method by which I could keep my hands warm in cold weather. Wear a pair of thick woolen gloves and over these a second pair made on the pattern of the former wearing gloves. (With a special comparison only for the thumb and all the fingers in one. I feel that the latter glove but for broken gloves this pattern is probably the best. I found probably better a more effective and certainly a better if W G drives his motor car. The second pair of gloves both pair must be loose and the outer pair must have separate fingers.

### INCOME TAX

Emoluments of April 1927

J P S. is resident in a medical office. The appointment was advertised as carrying a salary of £50 per annum, an unfurnished house valued at £50 per annum. The reduction of the authority making the appointment provides for an inclusive salary of £50 and this from this salary he

deducted £50 per annum as representing the value of the unfurnished house, etc." What should be the amount of the gross Schedule E assessment?

"J P S" rightly regards Mr Justice Rowlatt's dicta in *Cordy v. Gordon* as the source from which the answer should be obtained. We fear that the change in the terms of the resolution has weakened his case. In the first portion of his judgement Mr Justice Rowlatt appears to distinguish between (1) payment of a salary plus an emolument not convertible into money, and (2) payment of a salary on condition that part be spent in some prescribed fashion. *Tonnant v. Smith* settles the former case in favour of the taxpayer, but the judge seems to have inclined to the view that in the second case the taxpayer will normally be liable on the full amount on the "salary"—"he has been paid a salary, and what he does with the salary is immaterial." One point in our correspondent's favour is that the judge laid some stress on the fact that in the case he was dealing with the sum to be paid was variable, whereas the deduction from salary which "J P S" suffers is constant. It is clearly a distinguishing feature, but we think that, on the whole, the odds are against "J P S's" success.

#### New Practice

"RETURNING" has sold his specialist practice in London under covenant not to practise his specialty in England for five years, he will reside some distance from London and may do general consulting work, and also some work for the Ministry of Pensions.

"His income tax for 1928-29 should not take into account any results of the, then transferred, London practice, he will be starting a new practice, the income from which will, for the first year, be assessable at the amount of the fees earned in that year, less the expenses incurred in running them. With regard to expenses incurred partly for private and partly for professional purposes, the only guide we can give is to point out that the total should be reasonably divided according to the actual ratio of use during the year. The Ministry of Pensions work will apparently be such as to justify the inclusion of the emoluments with other fees as the product of general practice. On that basis our correspondent might fairly claim to include the car mileage of the journey to and from the Pensions Office as professional use, but his legal title to do so is not beyond doubt. If "Returning" does not put up a plate or set aside part of his house for professional purposes there is very little, if anything, that he can deduct as the expense incurred professionally by way of rent, rates, etc.

#### Locumtenent's Expenses

"W D M" was engaged as a locumtenent in 1926-27 and has since "settled down in practice." The inspector of taxes advised him to make one return, including locum and other earnings together, but now declines to allow him to deduct the expense of travelling about when doing locum work.

Strictly the "practice" earnings should be dealt with separately on the basis of the previous earnings of the predecessor, if more favourable to "W D M," but in either case the expenses of travelling about on locumtenent work should be deducted in arriving at an assessment on those earnings as one unit. The inspector's view seems to be based on the assumption that they are being dealt with under Schedule E as the earnings of employment, in our opinion that is not the correct basis of assessment of locumtenent fees, and, in any case, that is not the basis which is being applied, seeing that they are being assessed under Schedule D.

#### LETTERS, NOTES, ETC

##### FELLOWSHIP OF S. MICHAEL AND ALL ANGELS

We have received the following note from the secretaries of this benevolent organization:

"It is thought that members of the medical profession might be glad to know of a maternity home belonging to the Fellowship of S. Michael and All Angels a society existing for rescue work among girls of the educated and professional class. The fees are very moderate. All information can be supplied on application to the secretary, 5, Bloomsford Terrace, S.W. 1."

##### DISMEMBERMENT AND SHOCK

MR HAROLD HARTLEY, F.R.C.S. (Newcastle, Staffs), writes: Perhaps yet another quotation may be of interest. Razis an elder of Jerusalem to avoid capture by the troops of Nebuchadnezzar, attempted to kill him but through excitement "missed his stroke." He then ran and cast himself from the wall of the city, falling on his side. "And having yet breath within him, an angel, inflamed with passion, he rose up and though his blood gushed out in streams and his wounds were grievous he ran through the crowds, and standing upon a steep rock when, as his blood was now well spent he drew forth his bowels through the wound, and taking them in both his hands, he shook them

at the crowds, and calling upon him who is Lord of the life and the spirit to restore him these again, he thus died."—*Apocrypha*, II Maccabees, xiv, 37-46.

##### THE CAUSE OF VESICAL CALCULUS

DR. A. T. WATSON (C.M.S. Hospital, Annam, China) writes under date September 20th. In the *BRITISH MEDICAL JOURNAL* just to hand of July 30th there is an article by Lieut. Colonel R. McCarrison on the experimental prevention of stone in the bladder in rats. I thought that it was worth recording that to day a male Chinese child of 30 months was operated upon for stone and a calculus weighing 7 grams removed by the supra-pubic method. The child was still at the breast, though this was supplemented by rice and other foods. In view of the dramatic results obtained by Colonel McCarrison in preventing the formation of vesical calculi by adding milk to the diet of rats, this case, where the child had had maternal milk as its diet since birth, would suggest either that the maternal milk after the first year was very deficient in vitamins or that in the human subject the formation of calculi is not influenced either way by a diet of milk.

##### TOXICITY OF EPHEDRINE

DR. T. J. KITT (Stockport) writes: Ephedrine, which has been so well boomed in the lay press as a specific for asthma, still has its literature to acquire; therefore, I desire to record an experience which has just befallen me. The patient, a woman of 64 years, was given twelve half gram ephedrine tablets, with instructions to take one when the breathing became difficult. Two nights ago she sent to say that she was having asthma again, could she take more than one tablet? I replied, "Yes." I was called again at 3.30 a.m. to find that she had taken ten of these tablets in five hours without easing the asthma or apparently affecting her in any way.

##### A DISCLAIMER

We have received from Dr. A. C. MAGIAN (Manchester) the following letter, with a request for its publication:

I regret that recently an article purporting to be a personal interview with me and containing a highly sensational account of a lecture given by me to a medical society has appeared in the London press. The facts of the case are these. The wife of one of our members is also a press reporter to several daily papers. She read the circular sent to her husband, attended the meeting (she was not known by sight to me), and sent a report of my lecture to the papers for which she writes. The following morning before I was out of bed or had seen a newspaper someone, whom I took to be the publisher of a medical paper to whom I had sent an account of my lecture rang me up and asked me about certain points connected with it. I answered in good faith, and it was not until midday that I discovered the error. Later I tried to explain to some reporters who called that the lecture was a private one and must be closed, but my explanations only produced more "copy." I have written to the London and Counties Medical Protection Society and to the various people concerned.

##### CORRIGENDA

DR. R. J. CHURCH (London, W.) writes to point out that in the reports published last week at p. 879, some remarks on spinal anaesthesia were erroneously attributed to him. The only contribution Dr. Church made to that meeting was a minor query as to blood pressures, which was answered by the President, the two cases followed by paralysis of the rectum and incontinence were not reported by him.

DR. TIMPLE GREY (London, W.) writes: I am so substantially misreported on p. 877 of the *JOURNAL* that I am wondering whether I might ask you, please, to note what I did say, namely—that the judicial authority under the Lunacy Act must accept responsibility for the commitment of persons alleged to be of unsound mind, and that if the magistrates who at present sit for this purpose will not accept this responsibility, magistrates must be found—say a county court judge or a medical barrister—who will. This is what I had the honour to propose at Edinburgh.

DR. E. ROWLAND FOTHERGILL has called attention to two errors in his letter on "Contributory schemes: hospital club practice" published in the *JOURNAL* of November 12th (pp. 898, 899). The word "discussion," in the last sentence of the letter, should be "discussion," the resolution to which he referred is not that printed as a footnote to his letter, but the Brighton resolution published in the *SUPPLEMENT* of July 30th (pp. 74 and 75).

In the notice of the presentation to Dr. C. E. Stephens of a gold cigarette case on the occasion of his retirement from practice, published last week (p. 905), the initials were incorrectly printed.

##### VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 45, 46, 47, 50 and 52 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 48 and 49.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 203.

## The Huxley Lecture

## DIATHESIS

DELIVERED AT THE CHAPMAN CLINIC HOSPITAL,  
NOVEMBER 24TH, 1927,

Sir ARCHIBALD ARROD, K.C.M.G.  
D.M. LL.D. F.R.S.

REGIUS PROFESSOR OF MEDICINE IN THE UNIVERSITY OF OXFORD  
CONSULTING PHYSICIAN TO ST BARTHOLOMEW'S HOSPITAL  
AND THE HOSPITAL FOR SICK CHILDREN

"Men are called healthy in virtue of the inborn capacity of resistance to those unhealthy influences that may ordinarily rise unhealthily in virtue of a lack of that capacity. This passage from Aristotle's *Categories* written two thousand three hundred years ago may well serve as my text to-day."

We all know what we have in mind when we speak of health and disease, but it is not easy to frame definitions which shall embrace all that the terms denote. We still need to pay heed to the warning of that great teacher Thomas Watson, that disease must not be regarded as "a thing," or as the phrase goes "a separate entity" by which the body is possessed and dominated—something which can be contemplated apart from the body which it may invade.

As Aristotle's definition suggests, the state which we call health is one of unstable equilibrium maintained by means of a continual struggle, and no mere quiescent phase. Thus, in a recent lecture Andrievs spoke of the healthy body as one which "is not only perfectly adjusted to its surroundings but is capable of adjusting itself within reasonable limits to the circumstances of a rapidly changing environment." Disease on the other hand he defined as "a condition in which the body has fallen in lesser or greater degree, out of harmony with its environment." Another recent writer Draper defines disease as "an expression of reaction between a complex set of external circumstances, and an equally complex organism striving to survive in the midst of them." No narrower definition will suffice to include as it needs must do such widely different clinical and pathological pictures as those of small pox, malaria, scurvy, and myxoedema.

It is obvious that, as the word implies, disease is something appertaining to the patient and is neither an invading organism nor a poison introduced. Many of the outward signs and symptoms by which we recognize disease are evidences of the struggle which the organism is putting up against enemies which beset it, and as Andrievs pointed out in the lecture from which I have quoted, even inflammation and fever may be regarded as beneficial reactions. Bacterial infections do not necessarily cause disease only when the body begins to defend itself against attack does trouble arise. Nor must we forget, as we have been apt to do in recent years, that not all maladies come from without although the manifestations of those which do not are often provoked by external influences—trauma, exposure and the like.

It is an indisputable fact which has been recognized from early times, that some individuals, members of some families and of some races of mankind are far more liable than others to suffer from particular maladies, and around that basal fact have grown up the various doctrines of diathesis.

For some writers diathesis was nothing more than a predisposition to this or that malady, for others it was itself an extremely chronic disease which like the hidden mycelium of a mushroom bed, manifests itself here and there, and from time to time by outward signs. Others again gave a wider significance to the term as a liability to a group of allied affections, and spoke of an arthritic or a strumous diathesis. Some held that a diathesis might be acquired, but it was usually regarded as an inborn peculiarity. Lastly there have always been those who have looked upon the term 'diathesis' as merely a cloak for ignorance, a name masquerading as an explanation.

In medical writings of the first half of the nineteenth century the subject named diathesis and among its most exponents in this country were John A. Huxley and Thomas Laycock, who each had a wide influence in the Edinburgh school. The latter was claimed as diathetic diseases malady which we now know have hardly anything in common some of which are due to bacterial or protozoal invasion, others are due to the lack of some essential factor in the body.

Nor is it to be wondered at that the concepts of our fathers regarding the subject seem to us obsolete now when we read what they wrote upon it. It came to us in a fog for when their doctrines were formulated the theory of evolution had not yet emerged, the existence of chromosomes and the importance of the germ plasm were not suspected, the laws of heredity were just unknown, and hormones and vitamin had not been heard of. We who hold the keys which they helped to cut to fit, unexplored by them are well able to appreciate the pitfall which lay in their path.

The coming of cellular pathology and above all the growth of bacteriology and protozoology turned men's minds into other paths. Attention became concentrated upon the agents of disease rather than upon the constitutional factors which latter received but scant attention, the very conception of diathesis was discredited, and the word itself was relegated to the scrapheap of obsolete terms together with such words as "idiopathic" and "strumous."

Now once more the pendulum is returning from the limit of its swing, interest in constitution—which word has to a large extent replaced 'diathesis' and with a wider connotation—is reawakening more perhaps in other countries than in our own. A large literature in the German tongue has appeared in the past few years and to Naegeli's writings and to the work of Julius Bauer, a veritable storehouse of ideas and facts. I would express my indebtedness to American constitutional clinics are being established notably that of George Draper in which valuable work has already been done. In this country Hurst's *Role* and Ramsay's *Maintenance* have by their discourses quickened a new interest in the subject.

Despite the fact that in the *New English Dictionary* diathesis is defined as "a (permanent or required) condition of the body which renders it liable to certain special diseases or affections, a constitutional predisposition or tendency," we are little inclined to-day to admit a constitutional state or diathetic conditions, however long lasting which have been acquired and in this lecture I shall speak of inborn conditions only.

When I was honoured by the invitation to deliver this Huxley Memorial Lecture in Huxley's own medical school I determined that I would try to look at the doctrine of diathesis as it appears in the light of recent advances of science and to emphasize once more the importance of constitutional factors in connexion with the incidence and shaping of malady. With that aim in view I would ask you to detach yourselves as far as may be from the medical standpoint and to avoid for the moment the many sides in the struggle between man and his disease.

There are two main paths by which my subject may be approached, first by statistical and anthropometric methods on Caltonian lines. This method is being pursued in Draper's clinic. Draper who aims at approaching the subject from four different directions—physiological, psychological, pathological, and immunological—comes to the four parts of a Japanese research, although distinct form parts of a single problem. The second path is by study of particular examples. I will of the light which they throw upon the general problem. This might be styled an experimental method but the experimenter is not man but Nature. I will follow the second path that I invite you to walk with me to-day.

In pursuit of our inquiry we need to carry out the old brick very far to the chromosome into which in the work of J. B. Leathes, are packed from the beginning all that precedes if not our fate and fortune, at least our bodily character, ties down to the colour of our eyes. In the illuminating address from which I have quoted

Lenthes spoke of the chemical aspect of evolution as follows: "The deposition of matter in molecules or aggregates, unstable or incalculably variable, that has and retains the power of determining the deposition of matter not yet so disposed, in such a way as to conform to its own deposition, or to patterns which help it to exercise this power, is all that must be premised for the whole of evolution to follow." Such a conception would certainly not have been rejected by Huxley,<sup>15</sup> who as long ago as 1876 said that "to be a teleologist and yet accept evolution it is only necessary to suppose that the original plan was sketched out—that the purpose was foreshadowed, in the molecular arrangements out of which the animals have come."

It cannot fail to be that natural selection works through chemical as through structural modifications, nor can it be doubted that, as Huxley<sup>16</sup> maintained thirty years ago, the features in which an organism differs from type are foreshadowed in the germinal cells, and, indeed, in the complex molecules of which the germ cells are built up.

As evolution proceeds, from the single cell to the various of such units which constitute higher animals and plants, the somatic cells of which the various tissues are built up become specialized for the several purposes which they have to serve, the renal cells for their work and the hepatic for theirs, and in so doing lose at first part, and later almost the whole, of the power which the primary cells possessed of reconstruction and repair of tissues, such repairs as are possible are carried out by the underlying cells of the mesenchyme. Only the germinal cells retain the power of reproducing all the tissues and structures of the body, which renders possible the propagation of the species. Whatever may happen to the somatic cells affects the individual, but not the future of the race—just as in a hive the worker bees are specialized for the carrying out of their appointed tasks, but have no share in the continuation of the race, save in so far as they care for the fertilized queen, so may we think of the somatic cells as writing upon the needs of the germ plasma.

There is nothing at rest in the living cell, nor in the molecules of which it is composed, nor even in the atoms, with their restless electrons, which go to the making up of those molecules, and in the complex of physical and chemical changes which we call life there are infinite opportunities for departure from type. As evolution proceeds organisms are produced which differ in chemical structure as well as in form, until the proteins of a group of living things become so far differentiated that they behave as foreign proteins to members even of kindred groups. When that stage is reached interbreeding is no longer possible, the species has become established, and its main characters are thereafter maintained.

As the organism becomes more elaborated there are ever increasing opportunities of departure from type. As Andrewes says, "A chronometer can suffer from a greater variety of defects than an hour-glass."

Each one of us, and each such departure which he exhibits, is one of Nature's experiments. Huxley,<sup>17</sup> in an address delivered to the International Medical Congress in 1881, after speaking of the vital phenomena which furnish the normal and typical characters of the species, added: "Outside the range of these conditions the normal course of the cycle of vital phenomena is disturbed, abnormal structure makes its appearance, or the proper character and mutual adjustment of the functions cease to be preserved. The extent and importance of these deviations from the typical life may vary indefinitely, they may have no noticeable influence on the general well-being of the economy, or they may favour it. On the other hand they may be of such a nature as to impede the activities of the organism, or even to involve its destruction."

It is with unfavourable deviations that the student of diathesis is concerned, but if there were no beneficial ones there would be no evolutionary advance, progress could go no further, the species could, at best, be saved from regression. Unfavourable modifications tend to be elimin-

ated, because they diminish the capacity of the organism to conform to its environment, and among the factors at work in the elimination of the unfit none is more potent than disease.

A new departure may be both good and bad, and if the advantage outweigh the disadvantage it may persist. Thus, when man assumed the erect position, and gave up the hump-like support of the abdominal viscera which is an essential part of the vertebrate plan, he thereby laid himself open to a number of minor ills—varicose veins, herniae, and the like, but the loss was as nothing compared with the gain, which was no less than the mastery of inanimate Nature on this planet.

Modifications acquired during the lifetime of the subjects, as results of disease or accident, do not come within the scope of our inquiry. That they are not transmitted to future generations a great mass of evidence testifies, they concern the individual only, and not his family or race.

Mutations, the step-like variations which originate in the germ plasma, and are transmitted, are produced by addition to, subtraction from, or alteration in the factors of inheritance already present. The departure from type may be very slight, or so great as to justify the use of the term *per saltum*. Goodrich<sup>18</sup> pictures what may happen to a complex molecule by removal of an atom, or of an atomic grouping, and adds, "in some such fashion do we imagine the changes occur in the factors of inheritance."

Lenz<sup>19</sup> carries the same conception a step further, and suggests that on a physico-chemical view of the germ plasma it is not to be expected that it will undergo smooth, continuous changes, but rather that it will be changed in lesser or greater steps, by the removal or shifting of the positions of molecular groupings. I would venture one step further still, and point out that we know, from experimental breeding of *Drosophila*, that the same mutation may originate over and over again, in the same species, just as a given chemical reaction will be repeated as often as the necessary conditions are reproduced.

Some mutations are dominant in Mendel's sense, and others recessive, but the study of human inheritance on Mendelian lines is beset with many difficulties. For obvious reasons the proportions of normal and abnormal members in the small human families supply little reliable information, as compared with that afforded by the experimental breeding of plants and animals, and we are often driven to apply the knowledge which has been gained by such breeding experiments to human problems, despite the lack of numerical checks.

Thus albinism, a mutation common to man and lower animals, is shown by experimental breeding to be recessive, and the peculiarities of its incidence in man supply clues for the recognition of the recessive character of some other human mutations. We learn that a peculiarity which is wont to appear in several children of normal parents, and with quite unusual frequency in children of consanguineous matings, may be regarded as recessive. For, as Bateson pointed out long ago, a rare recessive character, to which both parents must contribute recessive genes, is far more likely to appear when parents are both members of a family which carries the recessive factors, and the rarer the anomaly the higher should be the proportion of such matings among the parents of those who exhibit it. Again, mutations which are transmitted through normal females to the males are regarded as sex-linked recessives.

On the other hand, a character which is handed down in a family from generation to generation, and affects a large proportion of its members, is probably dominant.

Some of the inborn and hereditary characters which originate as mutations are more obviously concerned with the structure of parts and others with their functions, and it will be convenient to consider them under these headings, but not to assume a sharp line of division between them. For if, indeed, all the potentialities of the future organism reside in the molecular arrangements of the germ plasma, we must assume that even structural anomalies have a molecular basis, and how greatly chemical factors may modify form is revealed by the study of

disturbances of the endocrine balance. Keith<sup>12</sup> has emphasized this, and not a few zoologists, notably Goodrich,<sup>13</sup> are ready to admit the influence of chemical factors upon animal structure, but we must be careful not to press such analogies too far for it is obvious that the malformations by defect or excess have little in common with the modifications of facial contour and bodily proportions which result from endocrine disturbances.

No two individuals of a species are exactly alike, and even monozygotic twins differ in their finger prints nor are the differences chiefly in structure. We human beings differ in a thousand ways—in form, in chemical life, in mental methods. Of many of the minor differences few of us are even aware and each of us is apt to think of himself as normal. In a mixed population such as ours all sorts of factors contribute to the average of the race and to its morbid liabilities. The time of life is not without influence the child has his own special maladies and his points of least resistance are not the same as those of the adult. Old people, too, have their special diseases and age confers a comparative immunity from other. Indeed we are faced with a problem of great complexity when we attempt to unravel the strands which go to the making of men.

Structural mutations are of all degrees. Some are doubtless improvements some may be classed as unimportant others, again, are obviously detrimental and some the most extreme are incompatible with survival. Minor malformations may be harmful in virtue of disfigurement which they cause or because they increase the risks of accident. When an important organ is malformed its function may be impaired and so life may be endangered as witness the graver cardiac defects and cystic disease of the kidneys. Once more a malformed part may prove a *locus minoris resistentiae* malformed cardiac valves are specially liable to be the seats of malignant endocarditis.

It would be easy to collect a number of examples of morbid effects of structural malformations but a very few must suffice. In his book *The Pedigree of Disease* Hutchinson cites spontaneous dislocation of malformed joints and the liability to intussusception which results from caecal mesenteric. Of far wider importance is the view put forward by Hurst who attributes the rarer appearances of the so-called hypertonic and dropped stomachs with the attendant differences in the gastric secretion to differences in the shape and length of the stomach. But it is something more subtle than the influences of anatomical anomalies which we have in mind when we think of diathesis or of constitutional liabilities to disease and I do not propose to dwell further upon that aspect of the subject to-day.

In the borderland between structural and functional anomalies lies a large group of diseases of which I propose to speak under the name of tissue defects seeing that they exhibit changes not in any individual structure or organ but in special tissues. To one large and important group of these often spoken of as heredo-familial diseases of the neuromuscular system Gowers<sup>14</sup> whose teaching was wont to suggest to his hearers fresh outlooks and new lines of thought assigned the name of 'abiotrophies'. Although inborn the maladies in question do not as a rule show obvious signs until after several years of life and thenceforward are progressive. Gowers pointed out that in some of them at least the nerve or muscle cells wither away like plants without soil, to be replaced by fibrous tissue—'tissue weed,' as he called it.

Some of the abiotrophies are dominants such as Friedreich's ataxia some are recessives and pseudo-hypertrophic muscular dystrophy is a sex-linked recessive transmitted by normal mothers to their sons.

The period of onset of such maladies is usually much the same in members of the same generation of a family, but there is a tendency for the onset to be earlier from generation to generation. As Mitt suggested in another connexion diseases which so behave tend to eliminate themselves—a virtuous circle, so to speak—but a sex-linked recessive ensures its own persistence.

The boundaries of the several diseases of the group are

not always clearly defined, and examples of more than one abiotrophy are met with in different members of the same family. In some cases or the myopathies defect of individual muscles are met with and in others areas of change have been found in muscles not obviously involved. Of less importance save as indications of structural instability are the miscellaneous malformations which are occasionally met with in association with an abiotrophy.

It has been pointed out by Martin, Julius Bauer and others that the abiotrophies are not limited to the neuromuscular system and are probably justified in including in this class certain maladies based upon hereditary abnormalities of the blood corpuscles red and white and especially congenital haemolytic jaundice. The brittleness of the red corpuscles in cases of that disease was first observed by Chauffard and is well known. Nageli also has observed that the erythrocytes which in the microscopic field appear to be microcytes are found nevertheless to exceed normal corpuscles in volume whence he concludes that they are more globular in form.

Nageli regards the abnormality of the red corpuscles as the primary feature of the condition which may only manifest itself by obvious signs under the influence of external stimuli such as infection or toxic agents. The haemolysis and splenic enlargement he regards as secondary phenomena and it is a well known fact that the fragility and abnormal form of the red corpuscles persist in greater or less degree after removal of the spleen. It will be mentioned however that there are those who hold that the primary trouble is in the spleen and that the abnormality of the corpuscles is secondary thereto. Congenital haemolytic jaundice is a typical family anomaly and behaves as a dominant Mendelian characteristic.

As tissue defects may also be classed certain conditions characterized by fragility of the bones. The warning signal of the best known of these is a blue colour of the sclerotics owing to a defect of the fibrous tissue of the sclerotics which allows the choroidal pigment to show through it. The anomaly has been met with in large number of members of the affected families and in successive generations. As they grow older the affected members who generally give a history of repeated fracture of bone on light provocation tend to develop osteosclerosis—an interesting example of the development of a progressive disease of sclerosis in the subjects of an inborn anomaly. The fragility would not appear to be due to any deficiency of lime salt in the bones but to a defect of the mesenchyme with a disturbance of connective tissue formation. More recently it has been revealed by x-ray examinations that in certain subjects the fragile bones cast uniform dark shadows as if solid throughout, as indeed they are in some cases. The fragility is ascribed to loss of elasticity and perhaps to loss of tubular structure. The condition which behaves as a recessive character and has been met with in children of first cousins with undue frequency is probably progressive, for various degrees of obliteration of the medullary cavities have been described. In advanced cases enlargement of the spleen and lymphatic gland has been observed, presumably to compensate for loss of bone marrow.

Of even greater interest from our point of view is the strange malady known as myositis ossificans progressiva. This too, seems to be an anomaly of the mesenchyme and Bauer suggests that the cells of the mesenchyme remain in the subjects of this disease the power which they normally lose of producing bony tissue. The bone formation occurs in the connective tissue in and around the affected muscles. Two features of myositis ossificans call for special mention. The first is the association with it, in more than 70 per cent of all cases, of congenital deformities of the great toes and in some cases of the thumbs also. The nature of the deformity is not so constant as its seat but the digits are usually shortened by suppression or a phalanx or by union of phalanges. This association is obviously some thing quite different from the occasional coexistence of miscellaneous malformations frequently met with but it is difficult to see what is the nature of the link between the malformation and the malady. The second point is early or recent or both primary transmission of myositis ossificans. A few instances

of its transmission are known, and in one remarkable case a father who had the digital deformities, but no myositis, had a son with identical deformities who developed myositis in childhood.

The tissue defects under discussion bear eloquent witness to the importance of constitutional factors in disease, but they have not in the past played any part in discussions on diathesis. Many of them, indeed, were little known, if known at all, when the earlier writers were occupied with the subject. They teach the important lesson that diseases which develop in later childhood, or even during adult life, may have as their underlying causes inborn anomalies of the germ plasma which may have been completely latent in earlier life, or may have shown a warning sign, such as blue sclerotics or the digital deformity of myositis ossificans. Nevertheless they do not conform closely to the conception of diathesis, they are, on the surface, too inevitable.

In the abiotrophies the tissue defects are the most potent causative factors, and the influence of external exciting causes is minimal. It may be that, as Rosenbach suggested, the vitality of the tissues involved is so low that even normal function overrules it. Such evidence as we have up to now as to the condition of the affected cells is almost wholly histological, and we do not know whether the trouble be due to some defect in the constitution of the cells themselves or to some abnormal substance in solution in the body fluids. The former appears the more probable explanation, and we possess one clue which may prove to be important—namely, the brittleness of the red corpuscles in congenital haemolytic jaundice and their peculiarities of size and form. These are clearly independent of the medium in which they are suspended, and as far as I am aware it has not been ascertained whether normal red corpuscles are rendered brittle by contact with the serum of a subject of the disease.

On the other hand, it can be established beyond doubt that in individuals whose metabolic processes are in some way deranged, the presence in the tissues of an abnormal product of metabolism or of a normal product in undue quantity, may give rise, under adequate provocation, to morbid effects of greater or less gravity. Here, indeed, is realized the underlying idea of most of the earlier conceptions of diathesis or predisposition, is of an intermediate state which, in the words of Germain Sézary, "n'est pas encore la maladie—mais qui n'est déjà plus la santé parfaite"—and which Jonathan Hutchinson described as "a condition of prolonged peculiarity of health, giving proximity to definite forms of disease."

In a lecture delivered as long ago as in the year 1855, W. H. Walshe<sup>4</sup> spoke of diathetic diseases as "apparently generated and sustained by an intrinsic blood poison, resulting from some perversion of the nutritive processes of the individual," a suggestion much in advance of the time at which it was uttered, but in the list of diathetic diseases which followed there were no signs of such prescience. In it were included maladies of almost every class.

If we are prepared to look upon the life of animals and plants as a complex of physical and chemical processes, and to recognize the importance of chemical factors in evolution, it was emphasized by Leitch in a recent address, we are bound to admit that the morbid predispositions of human beings depend, to a large extent, upon their chemical build and chemical life. Nor can we escape the conclusion that, seeing that differences can be shown to exist, some obvious and some subtle, in the metabolic processes of creatures of different genera and species, there must be differences, of like kind but of less degree, between the individual members of a species.

We should expect chemical mutations to be less obvious than those of form, but it is probable that they are not less numerous. A systematic search for such mutations would involve elaborate metabolic studies of large numbers of individuals, and much of the labour expended would probably be in vain. But just as one who carries out a systematic scrutiny of emergency notes would not fail to pick out a note with a wrong watermark, or one printed

upon discoloured paper, so some metabolic anomalies attract attention because they give some conspicuous sign, or, as in the case of pentosuria, are detected by response to some routine test in general use.

Some of the more conspicuous anomalies give rise to serious troubles sooner or later, and by the study of the more obvious errors of metabolism we gain insight into the possible effects of such deviations from the specific type, and by learning how a lesion or syndrome is produced in the few cases we may gain a notion of the mode of its production in the many.

In most instances the victims of metabolic anomalies show no morbid signs until the appropriate exciting cause comes into play, just as a sufferer from Raynaud's disease may spend his life in the tropics, unaware of his infirmity, which is revealed when he comes to a cold climate.

Among the diathetic diseases enumerated by Walshe cystinuria has a place. This anomaly had been known for half a century previously as a cause of calculus formation. We now know that cystin is one of the most important of the fractions of which protein molecules are built up—the bearer of the sulphur which they contain. Cystinuria is the sign of an error of protein metabolism in which other protein fractions are involved. A subject of this anomaly may live his life in ignorance of his infirmity, whereas a brother similarly affected may suffer almost continually from calculous troubles, often in an aggravated form. Cystin, in virtue of its insolubility in acid urine, is eminently suited to form calculi, and, given the necessary exciting cause, probably an infection of the urinary tract, the cystinuric will form stones. The presence of the crystalline deposit may favour the infection of the tract. Apart from this the anomaly has no obvious ill effects, even when tyrosine, leucine, xanthine, and putrescine are being excreted together with cystin.

Gout may be regarded as a diathetic disease *par excellence*, and it has found a place in all lists of such maladies. That it is hereditary has been known from ancient times, and it manifests itself by recurrent paroxysms, separated by intervals of apparent health. Like cystinuria gout may be described as a tragedy of insolubility, for it is hard to doubt that the tendency of uric acid to be deposited in the tissues as crystalline sodium urate is the leading factor in the attacks, as witness the tophi so often seen in the ears of its victims, and not seldom in and around their joints. Many factors contribute to provoke the attacks, such as seasonal influences, indiscretions of diet, overstrain, and injury, and the seats of the lesions are determined by traumata recent or remote, and even the special liability of the toe joint is probably due to the repeated mechanical insults endured by the only joint upon which we press in walking. Gout in a hemiplegic patient attacks the joints of the paralysed limbs.

In some members of gouty families very trifling provocation suffices to determine an attack, whereas in the immune a flagrant combination of all the exciting influences is powerless to do so.

The pathology of gout is hardly less obscure to-day than when my father found uric acid in the blood of gouty subjects eighty years ago. The majority of those who have worked at the subject hold that the underlying factor is an error of purine metabolism, but as to the nature of that error they do not agree. Others still maintain that the primary fault is one of excretion of uric acid due to a defect of renal function. On analogy the former explanation appears the more probable, but the evidence for renal origin cannot be dismissed lightly. It is a well known fact that the excretion of endogenous uric acid which is independent of diet, varies rather widely in different human individuals, and a systematic study of the amounts of uric acid in the blood and urine of children of gouty parents should yield interesting results. This much is certain, that in gout we are confronted with a highly hereditary malady, presumably based upon an inborn defect, the manifestations of which seldom appear before middle life.

The familiar osteo-arthritis of later life, which appears as the hip-joint disease of elderly people, Heberden's nodes, and the like, is often ascribed to an injury, or severe wear

and tear and in infection may be a contributory factor. In the great majority of instances there is no obvious underlying cause but in a few instances, at least the primary cause is an error of metabolism. Alcaptonuria the rare hereditary error of protein metabolism which is characterized by the presence in the urine of an aromatic acid, homogentisic acid derived from tyrosine and phenylalanine, was long thought to entail no evil effects but we now know that at the age of about thirty years the subjects of this anomaly show signs of blackening of cartilage and later in life they develop osteoarthritis. In these cases the articular disease shows peculiar features such as a pronounced stoop due to implication of the spine and a characteristic gait which are sufficient in themselves to rule out all other causes. In some families, notably one which Umber has described the joint trouble picked out the alcaptonuric members, whereas the normal brothers and sisters escaped. Here we have still more conclusive evidence that the morbid effects of an inborn error of metabolism may be very long postponed.

To take a more example. It is a familiar fact that individuals of the human race differ widely in sensitivity to light and other forms of radiant energy and that there have been evolved protective measures such as pigmentation, and to a less extent, linsities. Whereas the available evidence shows that exposure to light is a wholly beneficial, we know also that in certain cases exposure to light gives rise to diseases of the skin, and even of the deeper structures too. It has been shown moreover, that the introduction into the tissues of certain pigments, for the most part fluorescent substances, of which eosin is one may render an individual acutely sensitive to light. The pigments of the porphyrin group possess, for the most part, this property and such a pigment is present in traces, in the tissues and excreta of normal men. It is a tempting hypothesis that the traces may play an important part in connexion with the physiological actions of light and of ultra-violet rays.

In rare individuals porphyrins are present in excess and are excreted in abundance in the dark red urine and in the faeces. The bones become deeply stained, and the teeth also in some cases. Such haematomorphosis is congenital and recessive. Its victims are pitifully hypersensitive to light. When exposed to bright light they develop a skin eruption known as hydroa vacciniforme which produces deep scars, and brings about grave mutilation by destroying the senses of sight, and even trouble in deeper structures such as rigidity of the digits and deformity of the hand. All the evil effects may be avoided by protecting the patient from light.

It seems certain, on the other hand, that haematomorphosis is not the only cause of hydroa vacciniforme nor even its commonest cause, but it is significant that when cases of that affection are collated the recessive mode of heredity of the whole series closely resemble those of the porphyrinurias alone. It seems probable that in the cases without porphyrinuria the underlying cause is some other metabolic derangement, or even several such and that in the sensitivity of haematomorphosis to light we have a special illustration of a law of wide application.

In the conditions which have been referred to there is present in the tissues some unusual chemical product or a normal metabolic product in excessive dose in consequence of an abnormal arrest of metabolism which may be probably due to lack or some individual enzyme, the task of which remains undone. But just as lack of a vitamin or a hormone may bring about untoward results so it would appear that the mere absence of an enzyme may in itself be the underlying cause of morbid developments. Thus a disease probably results from the lack of the enzyme which brings about the formation of melanin but a much more striking example is afforded by that grave and remarkable disease, haemophilia, a typical sex-linked disease the central cause of which appears to be absence of a coagulative factor.

Hurst has suggested that constitutional achlorhydria which is not infrequently found in young children tends to run in families, and was detected by Bennett and Pale in four out of a hundred healthy students, is due to an inborn

error of secretion and I have little doubt that, as time passes the part played by hereditary chemical defect in providing the substructure of disease will prove to be much greater than in the present state of our knowledge it can be shown to be. On the other hand we need to beware lest such phrases as "error of metabolism" used without real justification, may become convenient cloaks for our ignorance.

The further we pursue the study of diathesis the more clearly do we realize its many-sidedness. New facts press at themselves at every step. On some of these the passage of time forbids me to say anything and to others I can only allude.

For example, it is by no means easy to draw a dividing line between diathesis and idiosyncrasy, and into the category of idiosyncrasy falls the remarkable hypersensitiveness to particular proteins which is so clearly linked up with the excretion of uric acid, the erythematous intermittent hydrarthrosis, and some forms of asthma.

Again I have said little of the converse of diathesis, the benign mutations which favour the individual in the struggle for existence. Difficult as it is to detect an error of the body chemistry by its evil effect which may be long postponed, it must needs be more difficult to detect the one which are harmless or have only good effects. Yet we can see how such favourable mutations have been utilized in the building up of the defensive mechanisms which are ready to be brought into play to counteract a poison introduced and which confer upon some individuals and on the members of certain families an inborn immunity partial or complete, from various infectious maladies. Nor have I said anything of what Draper calls the psychological part, the profound influences exerted by and through the nervous system in connexion with what are spoken of as functional maladies and the instability of the nervous system which is not uncommonly an inherited quality.

Indeed, this lecture of mine is like a jigsaw puzzle, some bits of which have been pieced together into groups which foreshadow the picture of which they form parts. But if it shall have served to throw any light upon the factors which underlie the conception of diathesis or shall help to reawaken interest in the constitutional factors which play so important a part in the incidence and shaping of disease, it will have attained its aim. Nor has it been wholly divorced from the practical side of medicine as the healing art for it tends to reveal that the better we understand the susceptibilities of our patients the better we shall help to stay what Francis Galton called "the steady and pitiless march of the hidden weakness in our constitutions through ill-health to death."

## THE ACTION OF EXPECTORANTS.

BY

J. A. GUNN M.A., M.D., D.Sc.

Professor of Pharmacology in the University of Oxford, President  
of the Section

When we take a broad survey of the field of therapeutics it would be fair to say that, though from one year to another there may be no dramatic advance, yet in the course of a decade or so, especially during the last half-century, there is hardly any branch of therapeutics which fails to show steady progress. This may be either in the way of discovery of new remedies, or in the more full and precise knowledge of the action and uses of older ones. When we think, for example, of such important groups as local and general anaesthetics, hypnotics, antiseptics, and specific remedies, instances of real advance in a few years spring to the mind. But there is one department of therapeutics in which little forward movement has been registered, not only in a decade, but hardly any even in the last half-century, and that is the group of expectorants. Indeed, I am not convinced that we are even so skilled in the use of expectorants as our grandfathers were, for, with less to learn, they had more time—and I sometimes think more enthusiasm—for observing at the bedside the action of drugs.

It may be profitable first of all to consider the reasons for this peculiar position in which the expectorants are placed. The first reason is the difficulty of measurement. When an effect can easily be measured, then advance is likely to be rapid. If it were as easy to determine the quantity of bronchial secretion as it is to measure the amount of urine, there would be by this time no such vagueness in regard to the effect of expectorants as still exists. In a case of bronchitis the amount of sputum may vary from time to time. It is difficult to get a control, and it is impossible to separate the sputum from the bronchial discharge. But in spite of these difficulties I venture to think that something more might be attempted in the way of actual measurement of the amount of sputum, so as to dispel the present confusion as to whether a substance increases or diminishes the bronchial secretion, or to discover in what clinical conditions an increase is certainly brought about, and how long it lasts. The chief clinical difficulty, however, is the absence of quantitative measurement.

But often where the clinical difficulties are great the problem can be solved by experiments on normal men or on lower animals. Here again, however, there are unusual obstacles in the way of estimating the effects of expectorants. For example, a distinguished physiologist, who had taken large quantities of ammonium chloride, mentioned to me that he had not observed any expectorant action from it, this is, perhaps, not so difficult to explain even if ammonium chloride has an expectorant action in disease. Normally we are quite unconscious of the existence of our bronchi. There is just sufficient secretion of the mucous surface to keep the passages moist, any excess of secretion is carried up by the cilia and swallowed. A healthy person need not cough, so that unless the secretion is so copious as to require coughing up—that is to say, is interfering with the channel—it is doubtful whether an increase of secretion would be brought to consciousness. On the other hand, in a patient with an inflamed bronchial mucosa with viscid sputum producing cough, a slight increase in the amount of secretion with lessened viscosity might enable the bronchi to be cleared at least temporarily, and the effect of an expectorant which would produce no noticeable effect on a normal person may be immediately discernible and grateful to a patient in such a condition. Normal people are therefore not good subjects for testing the action of expectorants. In laboratory experiments some of the difficulties met with in clinical observations can be overcome, but new ones are introduced. Measurement of the amount of bronchial secretion is easier. Such methods can be employed, for example, as applying small measured and weighed pieces

of absorbent paper to the trachea and comparing the relative increase in weight before and after the administration of expectorants. But other factors have to be reckoned with—for example, differences in reaction between a normal and an inflamed bronchus, the complicating effects of anaesthetics, and the differences between various species of animals. In brief, there are difficulties in the way of exact estimation of the action of expectorants, whether the experiments be done on normal or diseased persons or on laboratory animals.

Even the definition of expectorant is unsatisfactory. From its derivation the word originally meant something that aids the expulsion of a discharge from the chest, but it has come to be applied loosely to substances which either increase or decrease the discharge, and the word has also special associations with the treatment of cough.

## THE PHYSIOLOGICAL BASIS OF EXPECTORANT ACTION.

In order to understand the action of expectorants it is necessary to appreciate what is the physiological mechanism for protecting the air passages. As is usual with mucous membranes there is a double mechanism for this—a motor and a secretory. In the case of the thoracic air passages, with which only we are immediately concerned, there is an elaborate and highly ingenious motor mechanism, there are, in fact, three mechanisms. First, there is the propulsive movement of the cilia which line the mucous membranes, secondly, there is the co-ordinated reflex expulsive mechanism of cough, and lastly, there is the peristaltic movement of the muscle of the smaller bronchi. Now each of these motor mechanisms has its definite part to play in the scheme, the failure of one renders the whole mechanism defective, though not inoperative, because their activities overlap. They perform somewhat different functions, and are called into play under different conditions.

Let us take first the patient, continual movement of the cilia. The trachea and bronchi are lined with ciliated epithelium down to, but excluding, a short length of the terminal bronchioles. I remember, as a medical student, thinking that the propulsive action of microscopic cilia was one of those mythical forces that operate only in textbooks. It required only a slight experience of ciliary movement to alter this opinion. A class demonstration by Professor Schafer, in which was shown, projected by lantern, a piece of cork swept on by the ciliary movement of a strip of frog's gullet was an awakening and convincing demonstration of the power of ciliary movement. If properly aligned, a small strip of ciliated epithelium can be made to rotate a revolving drum. The ciliary movement is, in fact, a powerful propulsive movement, and it is this motor mechanism alone which normally deals with removal of bronchial secretion, cough is an exceptional and reserve mechanism. Continual secretion of mucus is necessary to keep the air passages moist, but with normal variations in this secretion the ciliary movement is competent to deal. It acts like a moving staircase, continually carrying up any excessive secretion till it reaches the throat and is swallowed. It has been calculated that this movement may propel solid particles at the rate of one inch a minute. The speed will vary with the size of the particles and with the viscosity of the secretion, but, under favourable conditions, the ciliary movement is able to bring up material from the very depths of the bronchioles in a few minutes.

A description of the expulsive mechanism of cough is unnecessary here. One point, however, which it is important to bear in mind is that the expulsive effect of cough is greatest nearer the larynx, and gets less nearer the lungs. Indeed, it has been stated that the expulsive force of cough affects the smaller bronchioles very slightly, if at all. It will be seen, therefore, that the smaller branches of the bronchioles, those which enter the lung itself, are in a perilous condition—they have no cilia, they are not reached by cough. It is here that the third motor mechanism comes into play. A definite peristaltic movement of bronchial muscle, as contrasted with a mere alteration in tone of this muscle, is supposed to be a property especially present in the muscle of the finer bronchi. Where cough and cilia fail this peristaltic movement takes their

\* A paper read before the Section of Therapeutics and Pharmacology at the Annual Meeting of the British Medical Association July, 1927.

place. If this be so there is here revealed, as in all the regulating processes of the body, an extraordinarily ingenious and concerted mechanism.

In regard to the second protective mechanism—the bronchial secretion—this is necessary to keep the bronchial surface moist and to dilute irritants, and for this purpose the bronchial mucous membrane is supplied with a great wealth of glands. We seem to have little knowledge as to the regulation of this secretion under normal conditions—as to whether, for example, the glands are capable of eliciting the consistency or the composition of the secretion or whether this remains uniform. If the latter, then the consistency will subsequently vary, for example, according to the extent of evaporation of water, and consequently with the dryness of the air or the quickness of respiration. It may be conjectured that if this evaporation be excessive and an undue acidity of the mucus result this acidity will irritate the mucous membrane and cause a reflexly increased secretion. So could the consistency of the secretion be regulated.

This motor and secretory mechanism is in great part regulated by the nervous system. Efferent fibres of the vagus pass centrally from the mucous membrane, efferent fibres of the vagus pass down to the bronchial muscle and to the secretory glands. The bronchial muscle is also supplied by efferent fibres of the sympathetic. These afferent and efferent fibres converge upon a somewhat hypothetical cough centre which is related to, if not actually an integral part of the respiratory and vomiting centres. The latter are apparently not under direct nervous influence.

It is beyond the scope of this paper to enter fully into the nervous control. It will suffice for the present purpose to recall that under physiological conditions the movement of the cilia together with a continual and regular secretion of the glands is necessary for maintaining the integrity of the bronchial mucous membrane. Under abnormal conditions when the mucous membrane is irritated by noxious particles or by too profuse or too viscid secretion this irritation stimulates the cough centre and there results reflexly either cough or increased secretion or peristaltic movement of the bronchioles or some combination of these. It is in consonance with the view that the expulsive effect of cough is effective mainly in the upper air passages that it is elicited so most easily by irritation of the mucous membrane of this area.

#### METHOD OF ACTION OF EXPECTORANTS

I propose to deal almost exclusively with the methods by which the bronchial secretion can be increased by drugs, especially with a view to suggesting reasons for some clinical differences in the action of expectorants of which no explanation seems to have been given. Expectorants may increase the bronchial secretion by acting in one or a combination of four different ways depending upon their site of action. Upon these differences can be based a physiological classification of them. They may act (1) reflexly, (2) by stimulation of the vagus centre, (3) by stimulation of the secretory (vagal) terminations, (4) by direct stimulation of the secretory glands. This classification is not to be regarded as a mere academic curiosity. It is upon differences in site of action that the superior suitability of certain expectorants for certain conditions largely depends.

##### 1 Reflex Expectorants

A large number of drugs which have no common pharmacological property other than that of being gastric irritants have in the course of time come to be used empirically as secretory expectorants when given by the mouth. Many of these drugs have been used as emetics in larger doses. That there is some association between an emetic and an expectorant action has been known for a century or more. So far as I can find Christison is the first to give something of an explanation of this when he stated (1842) in regard to ipecacuanha that "the pulmonary mucous membrane would seem to be often stimulated to increased secretion by repeated small doses, although nausea be not produced probably in consequence of the lungs sympathizing with a gentle stimulus and increased secretion of the gastric mucous membrane."

A more modern explanation of this is that the increased secretion of the bronchi produced by ipecacuanha and other members of this group is a reflex, the afferent stimulus for which is the irritation of the gastric mucous membrane, the afferent path the sensory fibres of the vagus, the centre the vomiting centre (or possibly a centre for bronchial secretion) and the efferent path the efferent fibres of the vagus going to the bronchial glands.

What is a little unusual about this reflex is that normally the afferent stimulus for reflex bronchial secretion is irritation not of the gastric but of the bronchial mucous membrane. But it is a characteristic feature of vagal reflexes generally that the efferent side of a reflex can be discharged by stimulation of afferent branches of the vagus other than those normally concerned with the reflex provided that this abnormal stimulation is of sufficient intensity and duration. This as is well known is equally true, for example, of the cough reflex. Cough can be induced not only by the normal stimulus which is irritation of the tracheal or bronchial mucous membrane, but by irritation of other afferent branches of the vagus—as, for example, in the ear pharynx or pleura provided that it is of sufficient intensity and duration. A large number of expectorants belong to this group. Ipecacuanha, tartar emetic, ammonium carbonate, quill and senega all owe their expectorant action, at least in part, to gastric irritation.

I wish to consider in regard to this type of expectorant action certain points to which I have seen little or no reference made. It is well known that reflex bronchial secretion can be induced by any of these gastric irritants with doses which are insufficient to cause actual vomiting, but only certain emetics have come to be used as expectorants for example clinical experience has decided in favour of tartar emetic and ipecacuanha in preference to copper sulphate or zinc sulphate. This preference is not accidental. A reflex emetic must possess certain qualities if it is to be suitable for use as an expectorant and those qualities can be illustrated by a comparison. Copper and zinc sulphate irritate the mucous membrane of the stomach by combining with the proteins of the mucous membrane of the stomach. It is a rapid chemical action giving rise to a sudden and rather intense stimulation of the afferent nerve ends, emesis if it is to occur at all takes place rapidly. These emetics cannot be administered repeatedly as their chemical action would thereby cause damage to the gastric mucous membrane. The action of tartar emetic and ipecacuanha on the other hand is much slower but lasts longer. When for example they are used as emetics the onset of emesis may be delayed for fifteen to thirty minutes during which time sensations of gastric irritation are experienced and vomiting is apt to be repeated even with a single dose. Moreover when repeated small doses are given no serious gastric irritation is produced. It is fairly obvious therefore that there are two qualities which an emetic must possess before it can be of practical value in small doses as an expectorant. In the first place it must not produce so gross or intense an irritation of the gastric mucous membrane as to cause serious or permanent gastritis when given repeatedly. In the second place this milder gastric irritation must be sufficiently prolonged to cause a reflex bronchial secretion of sufficient duration to make the administration of the substance for this purpose worthwhile.

There is another point in regard to expectorants of this type for which some explanation may be found. The statement that ipecacuanha is a more effective and more certain expectorant in children than in adults has been made so often by different observers that it must have some basis in fact. The pertinent fact may be that the emetic centre in children is more active and more easily stimulated than in adults. It is plausible to suppose that the effects which accompany gastric irritation of this type and which are accompanied by reflex stimulation of the expectorant action is once well established more easily in children.

The opinion has been widely held that ipecacuanha and tartar emetic have compared with potent purgatives a superior merit in acute bronchitis. A reasonable explanation for this would be that the former have a more direct

action, which would be of value in lowering the temperature in febrile cases. This added effect is not produced by potassium iodide to the same extent.

### 2 Central Expectorants

Bronchial secretion can be excited not only reflexly but also by stimulation of the centre in the medulla. As has been already pointed out, this centre is closely associated with the vomiting centre, and therefore emetics which act centrally can be used, in subemetic doses, also as expectorants. Ipecacuanha probably acts to some extent centrally, and possibly also tarts emetic, though they act mainly by gastric irritation. Apomorphine, however, acts entirely by central stimulation, and it has been used to some extent as an expectorant. It has not proved therapeutically so valuable as ipecacuanha, probably because its action is too transient.

### 3 Stimulants of Secretory Nerve-ends

A number of drugs are known which stimulate the terminations of parasympathetic nerves, and consequently stimulate bronchial secretion, among a variety of other effects. The only one of this group which has been used therapeutically is pilocarpine, or its active principle pilocarpine. The employment of pilocarpine for this purpose has been almost given up. Great accuracy of dosage is required in prescribing it, otherwise so many unwanted effects, such as constriction of the bronchi, oedema of the lung, profuse sweating, and cardiac slowing, occur coincidentally with increased bronchial secretion.

It is possible, however, that there may still be a limited field of use for pilocarpine if the necessary accuracy of dosage could be attained. It has been observed that, especially in children, the bronchial secretion is increased by pilocarpine before other secretions, but, seeing that there are so many safer expectorants, this fact, even if advantage could be taken of it, would hardly outweigh the disadvantages of pilocarpine, unless possibly in one condition. When the central nervous system is profoundly depressed it is possible that reflex centres like ipecacuanha are relatively inactive, whereas the action of pilocarpine, which is independent of the condition of the central nervous system, would be unaffected. In these circumstances pilocarpine might be the most reliable expectorant.

### 4 Direct Stimulants of the Bronchial Glands

It was at one time thought that nearly all expectorants produce their effects by being excited through the bronchial glands and increasing their secretion during passage through them. The action of the majority of expectorants has now been otherwise explained, but certain expectorants still act in this way. The most important of these is potassium iodide. Iodides, like chlorides, are excreted by the bronchial among other glands, but the action of iodides on secretions is not simply due to salt action, as is shown by the fact that in iodism there is a pronounced swelling and increased secretory activity of the nasal, lacrymal, and bronchial glands such as does not occur with chlorides.

The action of iodides, like that of pilocarpine, on the bronchial secretion is independent of the condition of the central nervous system, and they are very reliable expectorants. There are two points in regard to the clinical use of iodides for which no entirely satisfactory explanation has been given. In the first place, the opinion is widely held that iodides are less useful expectorants for children than for adults. A partial explanation for this may be that iodides lack the diaphoretic and antipyretic action of the ipecacuanha group, an action which is of value in febrile bronchitis in children. Secondly, iodides are believed to have a peculiar value in some forms of chronic bronchitis. It is possible that this may be due, though exact measurements are wanting, to a more prolonged action than ipecacuanha, for example. It is also possible that in chronic inflammation of the bronchi iodides may have some action in resolving inflammatory deposits, similar to the known action of iodides in resolving gummatous material.

### OTHER CLASSIFICATIONS OF EXPECTORANTS

Classifications of expectorants other than that depending on their site of action have been used. There seems to be no known pharmacological justification for the attempt to divide them into stimulant and depressant expectorants. For example, senega and squill are classed with the former, and ipecacuanha and tartar emetic with the latter. It is also a tradition that the former are more suitable for subacute and chronic bronchitis, the latter for acute bronchitis. Senega, at least, appears to act exactly like ipecacuanha and tartar emetic, by irritation of the stomach. It has no known stimulant quality, and until it is shown to possess this it is misleading to call it a stimulant expectorant or to regard it as differing in respect of its expectorant action, pharmacologically or therapeutically, from ipecacuanha. The expectorant action of squill is likewise due mainly to gastric irritation, though it may act on the centre as well. But the term "stimulant expectorant" was applied at a time when very little was known of the pharmacological action of expectorants. Seeing that, nearly a hundred years ago, Christison pointed out that "there is not, as some still imagine, any sound reason for avoiding it [squill] in acute affections of the chest on account of its supposed stimulant operation," the time would seem to be ripe for abandoning this division of expectorants into stimulants and depressants, as also for challenging the idea that there is any known reason for avoiding squill or senega in acute bronchitis.

Where squill does definitely differ from these other three expectorants is that it has a digitals-like action on the heart and is also a diuretic. It is especially in chronic bronchitis that these added actions would be likely to be of value. It is not improbable, therefore, that it required its reputation in chronic bronchitis for these added actions, which would be more likely to be displayed in the days when it was given in larger doses. But to regard it as having some kind of expectorant action different from ipecacuanha would seem to be misleading.

It would be beyond the limited scope of this paper to attempt to deal comprehensively with the many facts of the action of expectorants in regard to which our knowledge is deficient. As has already been hinted, this deficiency is, broadly speaking, of two kinds. One is the want of satisfactory explanation for the employment of a drug which has been handed down to us from an empirical age, and the other is incomplete knowledge of the physiological actions of the drugs.

An interesting example of the former is the use of hydrocyanic acid in cough. Hydrocyanic acid has been used for a long time as a common ingredient in cough mixtures, with the reputation that it "relieves an irritative cough." Its value for this purpose is usually scoffed at in modern textbooks of pharmacology, and the criticism is probably well founded that the doses given are too small to have any direct effect, either on the cough centre or on the bronchial tubes. This, however, does not negative its employment, and a consideration of its pharmacological actions and the history of its therapeutic use will perhaps place it upon a more reasonable basis. It was originally given not by the mouth but as an inhalation, and in the *British Pharmacopoeia* of 1867 there was a "hydrocyanic acid" for the latter purpose. I believe that this practice originated in the use of inhalation of cherry-lime water. As hydrocyanic acid is known to exert a local anaesthetic action which is especially marked on mucous membranes, there is at least the possibility that, when inhaled, it would exert this action on the upper air passages. Here again we seem to have no measurement of the dilution in which an effective sedative action of hydrocyanic acid would be produced, but in any case the original use of hydrocyanic acid in cough was based upon a known pharmacological action. The practice of administering it by inhalation was given up probably from fear of accidents with so powerful a poison. But it still has a reputation for relieving cough when given by the mouth, and there is a pharmacological justification for its use even when given in this way.

As has already been shown, cough and bronchial secretion can be excited by irritation of afferent branches of the vagus other than those of the respiratory mucous membrane, if this irritation is of sufficient intensity or duration, and the action of a whole group of expectorants is due to this. If a pharmacological irritation of the gastric mucous membrane can excite cough or bronchial secretion, it is difficult to see how a pathological irritation of the same surface can fail to do so likewise. Indeed, a "stomach cough," especially occurring in children, in whom the reflexes are more active, was well recognized by older physicians. The action of hydrocyanic acid may well be that when given by mouth, it relieves cough by its anæsthetic action on the pharynx and stomach checking in fact the very reflex which ipæacuanha excites. It could thus clear itself of a reputation for uncertainty because, having no direct action on the respiratory system (in these doses), it would relieve cough only when this was secondary to pharyngeal or gastric irritation. Bruntton who after preliminary scepticism convinced himself of the reality of a stomach cough, gave a plausible explanation for the occasional relief of cough by sodium bicarbonate.

The action of hydrocyanic acid has been considered at some length because it warns against the condemnation of therapeutic experience merely because no obvious pharmacological explanation can be given, especially as this is to be remembered when this scepticism regarding the usage of our forefathers is accompanied by an ignorance of their methods of administration.

The deficiency of our knowledge of expectorants however does not lie only in an occasional failure to give a reasonable explanation of therapeutic usage. We have much to learn also in regard to the physiological side, and an important example may be given. As is now well known the vagus nerve supplies afferent branches not only to the bronchial mucous membrane but also to the bronchial muscle. A drug like pilocarpine may cause not only increased bronchial secretion but also constriction of the bronchi. We seem to have no knowledge however as to whether when bronchial secretion is provoked by reflex irritation—as for example by ipæacuanha—constriction of the bronchi is simultaneously produced. It may be that the secretory fibres of the vagus are more easily excited reflexly than the motor fibres. We have even less knowledge of the peristaltic movement of bronchi or whether this is excited by expectorants. These problems could seem to be not insoluble by pharmacological method. Christy has pointed out in regard to ipæacuanha that "expectoration is never so unequivocally augmented when nausea is also excited." This has also been emphasized by others. It may be that this merely signifies that with larger dose of ipæacuanha there is a more copious bronchial secretion. It may be, on the other hand that when doses large enough to produce nausea are given something else happens and it is conceivable that this additional factor is a stimulation of the motor fibres of the vagus with a resulting peristaltic movement of the smaller bronchi. The conjecture is excusable in so far as it affords a basis for experiment.

#### CONCLUSION

The object of this paper has been to attempt to give a clear exposition of the physiological basis for the action of expectorants and to summarize the present state of knowledge of secretory expectorants upon this basis. Suggestions have been made to reconcile the tenets of clinical experience with the known pharmacology of the drugs concerned where this reconciliation seemed possible. In many respects our knowledge of the action of expectorants and of their relative values in different conditions is far from complete. Many of the points in dispute can be decided only by observation of the effects of expectorants in patients with respiratory disease though the contribution which the pharmacological laboratory may yet make is not exhausted. Here however is a field of investigation for which ample clinical material is available. It is a field in which the general practitioner can play an important part.

#### DISCUSSION

Dr H. WHITPIDGE DAVIES (Leeds) considered that ammonium chloride acted only by its gastric irritant effect. When large quantities of this drug were taken in order to produce experimental acidosis the subject suffered from very considerable nausea. Moreover, Halliwell had stated that in order to avoid emesis in experiments of this kind it was necessary to take it in very dilute solution. After absorption ammonium salts were converted into urea and the amount which could be excreted into the bronchi must be infinitesimal.

Professor R. J. S. McDOWALL (London) said that it was well known by larvælogists that the bronchi contracted during inspiration. He thought that Professor Cunningham's suggestion of combining the use of expectorant with adrenaline might well prove most useful.

### DISCUSSION ON IMMUNITY

#### I.—CERTAIN PRACTICAL ASPECTS OF IMMUNITY

By P. A. OBPEN, M.D.

Wellcome Physiological Research Laboratories, B. Ketcham Road

In reviewing the great amount of work being carried out in immunology and its vast literature the general practitioner medical or veterinary has a right from time to time to ask of the worker in the field what advance in medicine have resulted—advances so generally accepted as to be reasonably considered permanent and which he must therefore be prepared to use in his practice. It is arranged that as Professor Browning is dealing with the more attractive explanation of the phenomena underlying certain aspects of immunity I should deal with what we may call the practical achievement of immunology in the recent past and also survey briefly the tasks just ahead, since comparative medicine is represented at this meeting by a number of the audience in human and veterinary medicine side by side may not be out of place.

In endeavouring to estimate future tasks and possibilities of advance what lesson can be learned from the immediate past. During the past century the death rate in many human diseases has been much reduced. The first spring at once to the mind in the case of infectious and zoonotic diseases—typhoid, cholera, diphtheria, scarlet fever, and plague. I do not know that a case can be drawn from veterinary epidemiology as a parallel.

If we endeavour to draw up an order of merit in the who have achieved this reduction we shall have to give the greater honour to the hygienist and sanitarian who insists on general measures of comparison and sanitation, fresh air, a decent allowance of space for the individual—that is the avoidance of overcrowding—and the guarding of food and water supply. Next in order would come the immunologist who prevents himself with such a syringe and needle. Last of all the clinician who after disease assumes the barriers set up by the hygienist and vaccinologist to-day treats his patients with more knowledge than of old and reduces the death rate of his virulent specific remedies such as antitoxin as in diphtheria or with greater clinical skill until he to-day expects a mortality not more than half that of an earlier day.

But still the contribution of these three groups of medical workers bear the same relative proportion in the advances of the future. In considering these lines of advance the teachings of general epidemiology and particularly those of experimental epidemiology and of the influence of resistance on susceptibility interfere on the mind. We are beginning to have a clearer idea of these points thanks to the work of Topley and other particularly of the exact way in which isolation of infected

\*Presented at a discussion at a joint meeting of the Society for Pathology and Bacteriology and of Comparative Pathology at the Royal Meeting of the British Medical Association on Edinburgh, June 27, 1907. Professor T. J. Macleod was in the chair.

groups of people and the division of these groups into small units may control infection.

The condition of nutrition of the animal exposed to infection may be of at least as great importance as the "virulence" of the threatening organism. To judge from our own experience over some years, it is almost capable of direct proof that a stock of guinea-pigs, for instance, with certain potentially pathogenic bacilli present in their intestinal flora, and therefore in their surroundings, may remain healthy and not show an outbreak of the disease in question until the content in vitamins, salts, etc., of their diet be reduced beyond a certain point, or their living conditions be made unsuitable by exposure to extremes of temperature, uncleanliness, etc. Present evidence suggests that the outstanding advances of the future will come more from the immunologist than from the sanitarian or hygienist.

We are perhaps apt to forget how big a part the man with the syringe and needle already plays. Some striking figures can be gleaned from recent veterinary literature. Thus we find that probably upward of two to three hundred thousand pigs are injected yearly on the Continent with swine fever serum, the number in the United States of America being apparently greater, in Holland and California alone probably half a million fowls are vaccinated against avian diphtheria in a year of undisturbed season. East Africa and India last year used between four and five million doses, in one year about two million dogs in America and Japan were vaccinated against rabies, eight million cattle were tested last year in the United States with tuberculin. The only large figures in human medicine that may here comparison be the millions vaccinated with the various typhoid vaccines during the war and those protected against tetanus with serum, and the 500,000 children in the United States who have been tested by the Schick method or immunized with diphtheria prophylactic.

If, then, we agree that the future is largely with the immunologist or vaccinator armed with syringe and stainless steel needle, we may well consider what he is to inject and how he may best inject it.

#### "Bacterial Vaccines"

In human medicine we may expect universal acceptance of the statement that immunity by thorough vaccination can be conferred on those brought into contact with typhoid and the paratyphoid fevers, bubonic plague, probably cholera and dysentery, and possibly, under certain circumstances, pneumonia, in veterinary medicine—anthrax, blackleg, chicken cholera, leptospiral jaundice, and haemorrhagic septicaemia, and probably swine erysipelas and avian diphtheria or "roup."

How best can we immunize in these diseases—with live or dead vaccines, at what intervals? For human work living or "attenuated" living vaccines have been used, but have gone almost wholly, and probably permanently, out of use. Presumably, as recently ably argued by Ledingham, the living bacillus will produce a higher immunity than a dead one, and perhaps the ideal vaccine would be a certain non-pathogenic strain. But in human work the tide has set strongly against living vaccines, because of the obvious danger of the non-pathogenic agent becoming pathogenic.

In veterinary work this same danger is well recognized. The only living bacilli widely used are those for swine erysipelas, contagious abortion of cattle, and "blackleg" of cattle and sheep. We must freely admit that we do not know what is the best method of using these agents. An examination of many of the commercial swine erysipelas vaccines available reveals a wide difference in bacterial content. The wisdom of vaccinating against abortion is much debated. Some authorities maintain that dead vaccine does not give sufficient protection to be of use. Another branch of the living vaccine because it may introduce exact infection and abortion into a herd previously free. A longer action than in the United States of a bacillus apparently that in chlo. of pathogenicity may help in solving may have some relation present it must be freely confessed similar to the known so much that we must wait until gummatous material as ripe judgement. The plan States of trying to build up ous exclusion of "retectors" will

be watched with interest. For many years "blackleg vaccines" containing live spores of *B. chauvoei* were used. Of late bacteria-free "vaccines," the filtered muscle juice of artificially infected cattle, or the simple filtrate from a culture of the organism, have come widely into use.

Various living "non-pathogenic" cultures of *B. tuberculosis* have been used during the past two decades. The latest is BCG, an "attenuated" strain used by Calmette and Guérin, it is believed by these workers to be completely non-pathogenic and to possess considerable immunizing power. Although much evidence in its favour is being brought forward on the Continent, the efficiency and safety of this vaccine have not been widely accepted in Britain or America. Kraus and Gerlach in Vienna, and various speakers at the recent Russian congress, sound a note of caution. Until we begin to have some understanding of the immunological relation of tuberculin to tuberculosis comparable to our present conception of the relations between toxin and antitoxin in diphtheria, one venno to progress in our attack on this disease remains closed. It is curious that ordinary "exotoxic toxins" of diphtheria, tetanus, etc., are toxic for the normal as well as the infected animal, whereas tuberculin, of which 0.1 ccm. will readily kill a tuberculous guinea-pig, is innocuous to healthy animals in doses fifty times as large. A clear understanding of the "tuberculin" reaction would probably give us the key to much.

We have examples of the successful use of filtrates of bacterial culture in Dick toxin for immunization in scarlet fever in human medicine, and of filtrate ("artificial aggrassin") for immunization against blackleg in cattle. Filtrate is also used for protection against braxy, the winter disease of sheep caused by *Vibrio septique*. Whether the braxy filtrate can be made of such antigenic potency as to yield an immunity equal to that given by properly balanced toxin-antitoxin mixtures is not yet certain.

Toxin deprived of all toxicity has attracted much attention of recent years. With formalized diphtheria toxin, rendered completely toxic to animals, good immunity to diphtheria can be secured. Whether this "toxoid" or "antitoxin" will eventually replace toxin-antitoxin (U.S.A.) or toxoid-antitoxin (England) prophylactic mixtures for immunization against diphtheria in man and tetanus in animals must be left unsettled until further experience has been gained. Toxin "detoxicated" with仁emolite of sodium (Larson) has been introduced during the recent past. It is doubtful whether this will replace the ordinary mixtures and formalized toxin, but here also we must wait the verdict of further experience.

Mixtures of the toxin-antitoxin (or, better, antigen-antibody) type have given satisfactory results on the large scale clinically or in fully controlled laboratory experiments in protecting against diphtheria, tetanus, and "gas gangrene." Most of this practice has been founded on our knowledge of the use of mixtures of diphtheria toxin and antitoxin. It is therefore interesting to follow the course of clinical and experimental diphtheria prophylaxis, though the toxin-antitoxin mixture and toxoid-antitoxin mixture, formalized toxoid (that is, "antitoxin"), and "floccules." In the Ramon method of titration when toxin and antitoxin are mixed in certain "neutralizing" proportions a flocculant precipitate is formed. A suspension of these insoluble toxin-antitoxin floccules when injected into animals produces good immunity. Similarly formalized toxoid toxin or "toxoid" when mixed with antitoxin causes "floccules" to form, and my colleague Mr. Glenny has recently shown that these floccules also have high immunizing power. It is hoped that the "floccule" antigens may prove less liable to cause reactions in sensitive adults than the ordinary prophylactics and may possibly shorten the course of immunization. Recent work by Glenny (unpublished) suggests that by physical agents the toxoid can be dissociated from the toxoid-antitoxin floccules, and thus yield a much "purer" immunizing agent than has hitherto been available. An interesting special use of toxin-antitoxin mixture has been made by Drilling in his successful work on the prevention of lamb dysentery. Here the ewe is given two widely spaced injections of the prophylactic, the second as near to the date of lambing as possible,

in order that the concentration of antitoxin produced in the mother's blood may be high when the lamb is born, and the lamb may thus have enough antitoxin derived from the mother to carry it through the dangerous period of the first few weeks of its life. So far as I know, this is the only instance of the intentional and satisfactory use in human or veterinary medicine of the well known transmission of maternal immunity.

Antigen-antibody mixtures are met with, as live swine erysipelas bacilli and antiserum, and are given either as a mixture made immediately before injecting or injected simultaneously but separately into the animal's body. In milder pig and swine fever the mixture used consists of the blood of an infected animal containing the live filterable virus and the blood of an immunized animal containing antibody. Both methods are used on a very large scale and are successful when properly made materials are used. The *crum* of commercial animals is not used in veterinary medicine. In the prophylaxis and treatment of human measles the serum of human convalescents where available continues to be the most satisfactory results to bestow according to the method adopted either complete temporary protection to the very young or ill when given very shortly after infection, or active immunity to those receiving the serum at a late stage, when it will allow only a mild attack of measles to occur. This use of the antitoxin-containing serum at different periods after exposure to infection closely resembles that common in England in dealing with swine fever. Here the serum of immunized pigs is used. It is given to the pigs, in contrast, who may have accidentally received from their fellows does of the virus of unknown size at various periods before the serum was given. A degree of immunity found in practice to be satisfactory is given by this method.

#### How to Use Injections of Vaccines, etc.

Some materials may give a reasonable immunity after one injection—for example, vaccinia and black leg vaccine. Here one uses a large amount of material consistent with safety, and no question of spacing of injections arises. But when giving a "course" of vaccine or prophylactic the question of the best spacing and dosage arises. In immunizing horses against tetanus during the war Glenn obtained a remarkable result when he found that horses receiving an initial injection and allowed to rest completely for three months produced within six months of entering a serum stable a higher concentration of antitoxin than horses immunized continuously over the same six months. This result suggests that a revision of methods of spacing ordinary courses of prophylactic vaccines might be wise.

Amongst promising and interesting lines of inquiry in the recent past we may recall that on the mosaic structure of antigens particularly in the group of pathogenic intestinal organisms on the chemical aspects of immunity, the relation of undulant fever to contagious abortion and the continued speculation in connexion with non specific therapy.

*Intigens*.—Much work has yet to be done before we understand clearly the import of the recent work on rough and smooth colonies (agglutination) and bacillary (enloplasmic) intigens heat-stable and heat-sensitive agglutinogens and type and group specificity but already the man concerned with the diagnosis of the intestinal pathogens particularly of the food poisoning group in men or pigs and other animals must bear all this knowledge in mind and he who makes vaccines must inquire whether he is to make his most efficient vaccines from "smooth" cultures only. Apparently not typhoid vaccines in use are thus made.

The stimulating work on the chemistry of the proteins carbohydrates and lipoids in immunity continues to grow and the astonishing changes in specificity that can be produced by introducing chemical groupings promise to lead far towards a rational conception of specificity one of the greatest puzzles of immunity but up to the present there is not much result from this field which concerns the daily work of the practitioner. So-called non specific therapy continues to attract a considerable amount of notice and some bacteriologists proceeding from the assumption that clinical benefit may in some cases be definitely due to this

treatment, seek an explanation in the production of re-activation of the leucocytes, etc. Since there are many instances in which the curing of an infection can be obtained by the use of the substance in controlled animal experiments, the laboratory worker cannot have a first-hand opinion on any part played in clinical medicine by these methods of treatment.

With regard to vaccines themselves, there is nothing of new significance in recent work. The attractive hypothesis of Heist and Solis-Cohen if confirmed may be helpful in diagnosis and the making of antogenous vaccines. The authors hold that a patient becomes infected with certain bacilli because the blood has an unusually low power of resisting growth of that organism, the patient's blood in a culture tube will therefore allow the infected bacillus to grow faster than any other pathogenic organism. Thus the patient's blood used in the culture tubes or plates is a favourable elective medium for the infecting organism which one wishes to obtain.

Recent inquiries suggest that some attack of epidemic mild jaundice may be due to leptospira and if so can be treated with the corresponding serum. But even if they are not due to this organism the general teaching is that the practitioner would be prudent to treat all patients as potentially highly infective and to take the same precautions with regard to infection of food by urine, etc. as in an attack of typhoid fever. The intimate relationship between the *B. abortus* and the organisms of undulant fever and malaria does not as yet affect the general practice.

From the Pasteur Institute have come three methods—vaccination per os the use of B.C.C. and of antiserum for local immunization which are attracting great interest probably more on the Continent than in England or America. Apparently under careful controlled conditions it is possible to show that by giving dead vaccine (without bile) by the mouth to rabbits the animals immunized against otherwise lethal dose of *C. coli* bacillus as my colleague Mr. Runge and others have shown. In the earlier work the margin between the effective vaccinating dose and a dose dangerous to the health or life of the rabbit was not very large and the immunizing results were capricious. Bacteriologists are not all agreed that these difficulties have yet been entirely overcome so far as the typhoid vaccines are concerned the oral method though it is used in France and elsewhere has not established itself in England or America.

Foot-and Mouth disease which three years ago cost about £4,000,000 has become less of a menace at the moment. The immunologist can hardly claim any part of the credit due to the methods of slaughter used. We may hope that by a combination of application of the results of experimental epidemiology and the promotion of research work going on in England and in the Continent directed to a study of the condition of survival and propagation of the virus and of active immunization we may eventually be able to face outbreak of this disease with a less loss of life than in the past.

In canine distemper the conference in England of Carr's work on the *filterable virus* and the *filterable virus* promising results obtained by Dr. H. and Dr. H. lead us to hope that a practical method of immunization if not already here is also at our disposal.

Of actual achievements in the recent past veterinary medicine can count to its credit the successful protection against brucella. The two methods in use—vaccination with filtrate alone or with toxin mixture—apparently both give good results.

Among pig diseases a most interesting development in the recent past has been the big outbreak in the United States and the frequent failures of vaccination in the latter part of the epidemic probably due to the use of vaccine of low activity that had to be employed in the emergency.

In the poultry world there are instances of the infectious disease bacillary white diarrhoea of chicks which has seriously attacked in England and the results of research applied in the field. In one instance I knew a batch of 2,000 fine chickens was reduced to 27 in about two weeks. It is reasonable to expect that by the application of the agglutination test and perhaps the intradermic test, the

dangerous infected hens may be so dealt with as to free infected flocks from the disease, financial loss being kept low by wise disposal of flocks during the process of "cleaning up" flocks. Poultry breeders whom I have met are agreed that it will "pay" to build up "B W D-free" poultry flocks.

With much trepidation I venture to say that I think veterinary practitioners would here play a useful and proper part if they would take deeper interest in this work and train the poultry breeder to look to them constantly for aid in their troubles. In "B W D," by testing and administration, and in rousing by vaccination, the veterinary surgeon can promise practical aid of high value to the breeder. Veterinary surgeons on the Continent and in America find it well worth while to pay constant attention to these diseases.

International and State control of immunological materials tends to increase. The new Therapeutic Substances Act will control all such materials used in human medicine. In passing I may remark that examination for some years of various veterinary "biological products" leads me to say that at least as strong a case can be made out for the need of control of such materials used in veterinary as in human medicine.

In reviewing recent work in practical immunology to me the two greatest puzzles seem to concern tuberculin and local infection in the presence of circulating antibody. I have spoken earlier of the baffling relation between tuberculin, the tuberculin reaction, and infection with tuberculosis. The second problem arises when we remember that it is possible to immunize a horse or rabbit against the pneumococcus until a small quantity of its blood will protect a mouse against many lethal doses of live pneumococcus, and yet the horse or rabbit may have a damaging local progressive infection in the heart valves or elsewhere.

Prish and Okell have shown that we can give scarlet fever antitoxin to a rabbit and so protect it against a dose of live streptococci that will kill a control rabbit in twenty-four hours, and yet the rabbit injected with the serum, though it remains quite well for perhaps a fortnight, will most probably later show an inflammation in the joints, which are then found to be infected heavily with apparently the streptococcus originally injected. The obvious explanation that the local nidus is shut off from the general circulating antibodies may be sufficient, but it does not meet all our doubts. The problem has an obvious bearing on the inefficiency of scarlet fever antitoxin for the relief of late septic complications despite its clear curative effect in the early treatment of scarlet fever.

In conclusion, the immunologist has reasonable ground for pride in the achievements of the immediate past and a confident hope that continued work will give further advances in the control of disease.

## II—BIOLOGICAL PRINCIPLES IN IMMUNITY

BY

CARL H. BROWNING, M.D. GLASGOW,

Gardiner Professor of Bacteriology, University of Glasgow,  
Director of the Laboratory of Clinical Pathology,  
Western Infirmary, Glasgow

FUNDAMENTAL in their importance were the discoveries by Behring and his co-workers that antitoxins appear in an animal as the result of immunization with soluble bacterial toxins, and that passive immunity can be conferred on a susceptible individual by injecting the serum of one which has in this way been rendered actively immune to toxin. The existence of passive immunity proves decisively that in certain cases the cell-free body fluid carries the immunizing property, or antibody as it is called. The earlier observation of Nutt<sup>1</sup> that the tissue fluids of normal animals may possess bactericidal properties also stimulated the analysis of antibacterial immunity, and it is now known that the lethal effect of an immune serum is brought about by a remarkable dual mechanism consisting of the specific

antibody and a labile normal function of blood plasma, the complement. The detailed study of these phenomena of immunity, extending over upwards of thirty-five years, has shown that they depend upon a general biological process which is worthy of attention on account of its great theoretical interest as well as its practical value. It has become evident that antibody production represents a response of living animals—at least of the higher forms—to the presence in their tissues of various foreign substances, poisonous or non-poisonous, dissolved or particulate (cells), which are classed as antigens. It is proposed to deal here with those aspects of the subject which are important on account of the biological principles involved and in which recent work has contributed materially to our knowledge. Accordingly, the following questions will be considered: (1) Antigen-antibody reactions, the variations which the antibody may manifest, the evolution of specific antibodies, the role of the reticulo-endothelial system, the nature of antigens, and specificity. (2) The part played by immunity phenomena in chemotherapeutic action. (3) Blüch's receptor hypothesis.

#### ANTIGEN-ANTIBODY REACTIONS

When an antigen and the corresponding antibody are brought into contact *in vitro* the evidence of reaction is often manifested by physical changes in the mixture, such as precipitation, lytic action, etc., which are so evident that it is necessary to remember that they may not represent the essential phenomena, but merely subsidiary results. Bozetti's fundamental experiments on the mechanism of agglutination of bacteria by an antiserum proved that the flocculation of the organisms—which is in this case the visible effect of the interaction—is due to the salt content of the fluid. When the salt is absent agglutination does not occur, hence the specific part of the phenomenon—namely, the union of antibody and antigen—might escape detection in the absence of a suitable indicator. The far-reaching consequences of this conclusion have gradually been appreciated. Now it may be stated that the manifestations of antigen-antibody reactions, so far as they are observed *in vitro*, depend mainly upon the accompanying physico-chemical conditions or "indicators," and are paralleled by the reactions of other colloids. On the other hand, the essential alterations consist (a) in the removal from the antiserum of its characteristic property (antibody), as when it is treated with a sufficient quantity of a particulate antigen, and (b) in alterations in the characters of the antigen—for example, loss of toxic action—which are due to the latter having combined with some constituent of the antiserum, the proofs being supplied by Martin and Cherry's experiment showing that toxin after the addition of the corresponding antitoxin ceases to be filterable, and also by the demonstration that the combination can be dissociated—for example, the dissociation of toxin from antitoxin or of haemolytic immune body from sensitized red corpuscles. Since there is in many cases evidence that combination of the antibody with the antigen does not cause the latter to be decomposed in any way, therefore a close analogy with ferment action is lacking.

Among the indicators which render antigen-antibody reactions evident an important part is played by cholesterol and possibly by other lipoids. As Browning, Cruickshank, and Mackenzie originally showed, cholesterol intensifies the complement fixation observed in the Wassermann reaction, likewise flocculation of tissue lipoids by syphilitic serum becomes apparent when cholesterol is added to the tissue extract, and cholesterol has a similar effect in the reaction between Forssman's antibody and extracts of heterogenous tissues. The influence of lipoids as indicators has been strikingly demonstrated in a converse manner by Hartley's carefully controlled experiments. He has shown that antitoxic serum extracted with alcohol and ether in the cold no longer flocculizes when mixed with toxin in Ramon's test, although, as Hardy and Gardner originally noted, the treated serum has lost none of its capacity to neutralize toxin when tested *in vivo*. Again, precipitation fails to occur when a serum and the homologous antiserum are extracted and then mixed (although normal serum so treated retains its power of leading to precipitin formation

when injected into an animal. These reactions apparently require lipoids to render them obvious (since the mere addition of the extracted material does not restore the original conditions, as tested by the precipitation reaction, the effect of the lipoids is obviously of a complex nature). On the other hand, an extracted antityphoid serum agglutinates *T. typhosus* in as high dilutions as the untreated serum and an extracted haemolytic immune body has lost none of its sensitizing action, so that here the serum lipoids are not essential.

The role of lipoids in immunity reactions is however not limited to their action as indicators, as will be seen later they may constitute the essential part of the antigen (Landsteiner's "haptens") so far as concerns specific reactions with antibodies *in vitro*. Also, the remarkable effects of certain lecithins in increasing or supplementing the activity of complement or complement components discovered by Cruickshank and Mackie must be borne in mind. Examples such as those quoted above, however, show that in order to demonstrate antigen-antibody reactions it may be necessary to adjust the physical conditions precisely and to have suitable indicator substances. In the case of flocculation phenomena—for example the Sachs-Georgi reaction with syphilis serum—both these factors play an important part. Here the preparation of lipid emulsions in a suitable state of instability is essential but may depend on conditions which are difficult to control. These phenomena are now being closely examined by the quantitative methods of colloidal chemistry, but it must be remembered that the immunity reactions are characterized by the element of specificity which is not yet capable of explanation in physico-chemical terms and if the investigations are to be fully fruitful this specific element must never be neglected.

#### Variability in Antibodies

It is of great importance to determine whether the response of the animal to the introduction into its tissues of an antigen which is summed up in the term "antibody production," is capable of qualitative as well as quantitative variations. Muller had held that such was the case for agglutinins the combining power of which increased during the process of immunization. Pick and Schwoner and Hirus insisted in the case of diphtheria antitoxin that different serums might be distinguished not merely by their relative richness in antitoxin as measured by Ehrlich's method but that the molecules of antitoxin in one serum might possess a greater affinity for toxin (avidity) than the molecules in another serum. At the time, however, the evidence on the point was inconclusive. In the case of a thermostable haemolytic immune body (rabbit or corpuscles) it was proved by Browning and Wilson that a qualitative change did occur in the course of immunization. The "immature" antibody obtained at an early stage when added to the red cells in certain multiple of the minimum haemolytic dose was deficient in the power of leading to fixation of an increased amount of complement as compared with that fixed under the influence of a single dose. A property possessed under similar conditions by the mature immune body (Muir). Further advance in the investigation of such problems was stimulated by Ramon's discovery that specific flocculation occurred on mixing concentrated toxin and antitoxin in suitable proportions and that, as a rule, the precipitate formed most rapidly in mixtures which were practically neutral when tested in animal experiments. Now Ramon observed that the rate of flocculation might differ greatly when the same specimen of toxin was mixed with different specimens of antitoxic serum and he concluded that this phenomenon was related to difference in the avidity of the respective antitoxins. Rechin, Maden and Schmidt have stated that antitoxic serums which flocculate toxin rapidly are more effective as curative agents than those which bring about flocculation slowly—that is the number of antitoxin units as measured by Ehrlich's method which is required to effect cure of rabbits which have previously received toxin, is smaller in the former case than in the latter.

The question remains as to whether the antibody molecules differ in themselves or whether other constituents of the serum are responsible for the differences. In the case of haemolytic immune body investigated by us it

appeared that the molecules of antibody underwent change, since in the particular animal the differences depended on the stage of immunization and were independent of the concentration of antibody in the serum. Again Muir, by injecting the same species of blood corpuscles into different species of animals, obtained haemolytic immune bodies which showed qualitative differences as regards effectiveness in leading to lysis by the same complement, although they combined with the same receptors of the antigen. Lojane demonstrated that the avidity of a natural antibody, the haemolysin for guinea-pig red cells present in ox serum, was increased temporarily after filtration through a Berkefeld filter this result was independent of any alteration in hydrogen ion concentration. Glenn and Okell found that while the flocculation rates of antitoxic serums derived from different horses varied greatly, the rate for a given animal might remain fairly constant although the antitoxin content of its serum underwent marked increase. The observation of the Danish workers also, that the curative power of an antitoxic serum probably suffers diminution in relation to the content in immunity units, when it is concentrated by salting-out suggests that other constituents exert some influence. Glenn and his co-workers have shown that with the serums of different horses there may be a marked discrepancy in the ratio of the amount of antitoxic serum which produces optimum flocculation *in vitro*, to that which neutralizes toxin as tested *in vivo*. In addition, their finding of two zones of flocculation—a rapid non-specific and a slow specific one—also points to the interfering action of other constituents of the serum. Accordingly, there is a considerable amount of evidence that the behaviour of antibodies may be influenced by other factors associated with serum. But the existence of qualitative differences among antibodies which combine with the same receptors of an antigen cannot be doubted.

#### The Fixation of Specific Antibodies

The introduction into the tissues of certain substances (antigens) results in the development of specific antibodies. This generalization requires very great qualification in detail since in the class of antigens all degrees of effectiveness in the stimulus to antibody production are met with again species races and individuals vary in their response to a given antigen. These considerations will not be discussed here. In a particular animal however the amount of antibody present in the serum at a given moment may be influenced by non-specific factors—for example the effect of injecting metallic salts—as appears from the work of Walbum—but the essential stimulus is the original injection of the specific antigen. In attempting to conceive the nature of the process of antibody production it is necessary to bear in mind the occurrence of natural antibodies. These in many cases cannot be related to any specific toxin. Thus the lytic antibody for sheep corpuscles found in human serum or that for ox corpuscles in guinea-pig serum would seem simply to be metabolic accidents. The behaviour of natural antibodies has no on the whole been investigated in great detail apart from Ehrlich and Morgenroth's original work on haemolysins and that of Landeiner and his co-workers (Reich, etc.) on haemagglutinins.

Dunlop has recently made an extensive study of the phenomenon of complement fixation produced by adding typhoid bacilli to normal guinea-pig serum (private unpublished) and as the property seems to throw light on the evolution of antibody-ance it will be discussed more fully. The results were as follows: (1) That a guinea-pig serum when present in a neutral or a concentration is deprived of its haemolytic complement by treatment with typhoid bacilli at 37°C. and for 24 hours but not all have a similar action. (2) Serum which has been treated with excess of typhoid bacilli at 0°C. (the latter then being removed by centrifuging) does not lose its complement when in contact with further quantities of typhoid bacilli at 37°C. (3) Typhoid bacilli which have been treated with guinea-pig serum at 0°C. or having been killed and resuspended in saline are found to lose their size

THE BANNER, NOV 26, 1917, ALBANY, N.Y.

so that when one adds to them serum treated as described under (2) the complement of the latter is removed (4) Again, guinea-pig's serum treated with sensitized stomata (blood cells previously heated at  $56^{\circ}\text{C}$  which have been placed in contact with the corresponding immune body), although it loses its complement, still retains the typhoid antibody, this is shown by the occurrence of complement fixation when the serum so treated is added to typhoid bacilli along with complement prepared by method (2)

From these results it would appear that one is dealing with a natural typhoid antibody. The non-specific properties of this antibody, however, are of great interest, for it may be removed by a variety of procedures, while the hemolytic complement of the serum, which is in extremely labile function, remains intact. (a) The typhoid antibody may be removed at  $0^{\circ}\text{C}$  by organisms other than *B. typhosus*—for example, *B. coli*—although the latter did not lead to complement fixation at  $37^{\circ}\text{C}$ . (b) Contact with coal-dust or powdered glass at room temperature also removes the antibody without affecting the complement. (c) The antibody may disappear from a serum which has been kept for several hours at  $37^{\circ}\text{C}$ , although the hemolytic complement is not affected by the treatment. On the other hand the antibody in the guinea-pig's serum which has been treated with sensitized stomata may withstand heating at  $56^{\circ}\text{C}$  for half an hour. Accordingly, the phenomenon investigated by Dunlop affords a striking example of a property of serum which has many of the characters of an antibody, and yet lacks the strict specificity and the stability of antibodies developed in response to immunization procedures. In this connection it should be recalled that Thiele and Embleton, on tracing the development of a hemolysis after the injection of foreign red corpuscles into rabbits, concluded that the only form of hemolysis is thermolabile and incapable of being reactivated by adding complement (in which respect it resembles many natural hemolysins), and that it was difficult to distinguish from complement. At a later stage the hemolysis was differentiated into complement and immune body, the latter, however, being at first thermolabile.

As appears from the work of Tineguchi and others, the changes in the serum in syphilis which lead to positive Wassermann and flocculation reactions are most probably of antibody nature. Now Sugden and Williams (privately unpublished) in analysing the action of serums (previously heated at  $56^{\circ}\text{C}$ ) on the "antigen" (alcoholic herit extract plus cholesterol) have found that syphilitic ("positive") serum differs from "negative" serum only in a quantitative manner, the former causing precipitation with a wider range of concentrations of sodium chloride than does the latter. It is especially noteworthy that this flocculation effect occurs with concentrations of serum which, on the analogy of the ordinary protective colloid phenomenon, might be expected to show no flocculation. Therefore there appears to be some specific feature in the reaction of serum with the lipid "antigen" which is a general property of serum, whether normal or syphilitic. Accordingly, the evidence as a whole indicates that a common prototype of immune antibodies exists normally in blood plasma in a relatively undifferentiated state, and that in some way specific characters and avidity are impressed on it or undergo intensification in the course of immunization with an antigen. This conception, which has much in common with views put forward at an early period by Landsteiner and others, finds further support in the observations of Benjamin and Witzinger and Doerr and Berger on active sensitization, and of Kriess and Hermann on the production of antibodies. According to these observers the introduction simultaneously (or nearly so) of two antigens may cause suppression of the immunity response to one of them. It must be noted that Ehrlich's receptor hypothesis is not contradictory to the view of an undifferentiated antibody prototype, since receptors are liable to qualitative as well as quantitative changes.

The question arises here as to whether the serum antibodies and complement which participate in immunity reactions may properly be called substances or whether

they are merely states of the serum components. As regards the specific immune antibodies there seems little doubt that one has to deal with substances. Improved methods of isolation, based on those of Kosikari or Hinton, may eventually yield antibodies in a pure state. Kosikari found that hemolytic immune body which had combined with the homologous red cells could be dissociated by treating the latter at  $55^{\circ}\text{C}$  with saccharose solution and then removing constituents of the corpuscles by extracting with ether (the sugar, etc., finally being removed by dialysis). In the case of the complement the conditions are more complex. In a given serum complement is not a homogeneous entity, also its toxic and combining properties vary independently. The separation of complement into so-called mid-piece and end-piece by Ferrata and others does not represent an analysis into fractions with constant well defined characters. Later, third (Ritz) and fourth components (Gordon, Whitehead, and Wormald) have been described. It has been shown by Browning and Mackie that the complement function may be distributed over a number of the fractions into which the serum proteins can be divided. Accordingly complement may be, in part at least, a state of plasma and serum rather than a substance (a view also held by Sachs).

### *The Role of the Reticulo-Endothelial System*

When a considerable volume of blood is removed from an immunized animal the newly formed plasma may contain at least as much antibody as was previously present. This well established fact points to the secretion of antibodies into the blood. Since the fluid content of the vascular system depends so greatly on the endothelium lining the vessels it has been concluded that these cells are the source of antibodies. The vascular endothelium in certain situations, together with other cells of similar nature in the organs which are all grouped under the loosely conceived term of "reticulo-endothelial system," possess also marked powers of accumulating in their interior particulate matter, including bacteria, as well as certain dissolved colloid substances (vital stains). The attempt has been made, therefore, to determine whether these cells play a significant part in the defence against infection by filling them with inert material and then injecting either the antigen or an infective agent. Where an antigen was injected the course of antibody production might be interfered with, where the animal was inoculated with a pathogenic organism its resistance might be altered. The conclusions reached by different observers have been at variance (cf. Bickling with Rosenthal and his co-workers). As regards resistance to a general infection Cappell (unpublished) carried out a critical experiment, he injected two series of mice with isomul-blue and tyram-blue respectively, three to five doses as large as could safely be given being injected subcutaneously at weekly intervals, and eight or nine days after the last injection the animals were inoculated intraperitoneally with varying amounts of virulent pneumococci. The range of doses of the organisms was such that in the control series of normal mice the individuality of the animals played an important part in determining whether or not an acute fatal septicaemia would follow. The results showed that there was no gross alteration in resistance to infection which could be attributed to the vital staining or so-called "blockade" of the reticulo-endothelial system. The striking effects which have been recorded by some workers refer mainly to numbers of animals too small to be conclusive, and the operative and other procedures usually lack adequate controls. It is very doubtful also whether it is possible to throw this system of cells as a whole out of action by any of the methods employed, since they are capable of rapid multiplication. In fact, Ledingham has shown that by infiltrating in areas of a rabbit's skin with Indian ink, which leads to local stimulation of the reticulo-endothelial cells, the intravenous response to vaccine introduced at this site may be completely abolished. Accordingly, although it would appear that the methods of experiment have not yielded conclusive evidence on the part played by the endothelial cells in immunity phenomena in general, one cannot doubt their importance in this respect.

### The Nature of Antigens

Until recently the evidence indicated generally that foreign protein substances or constituents inseparable from these were alone capable of giving rise to antibodies. Although Ford had developed a powerful antiserum to rabbit haemolysin a glucoside by injecting the latter into rabbits and Kurt Meyer had stated that antisera obtained by injecting rabbits with extracts (waters) of tapeworms fixed complement in the presence of alcoholic extracts of the worms little regard was paid to the phenomenon. Later however attention was directed to the specific lipoids when it was observed that the lytic immune body for sheep's red corpuscles which Forssman had developed in rabbits by injecting guinea pig's organs (Forssman's antigen) reacted in vitro with alcoholic extracts (lipoids) of tissues containing the Forssman antigen. It was shown that the lipid emulsion combined with the antibody (Georgi Taniguchi). Thus if an alcoholic extract of tissue containing Forssman antigen was added to Forssman antibody the latter became fixed and so was prevented from sensitizing sheep's red cells when the mixture subsequently introduced into the mixture. Complement fixation and flocculation are also manifestations of the reaction. The reacting constituent of the extract with the boiling of the alcoholic solution for several hours it resides in the leathier fraction of the extract—that is the portion precipitated by acetone from the etheral solution (Taniguchi). Similarly prepared alcoholic extract or the separated lecithin fractions derived from tissues which led the Forssman antigen fail to react with the Forssman antibody *in vitro*. Although these specific antibody reactions occurred in the test tube, the reacting lipoids when separated by extraction of the tissues with alcohol were found to be incapable of leading to the development of the antibody *in vivo*. But Landsteiner showed that a mixture of the lipoids with a foreign protein (pig's serum) when injected into rabbits caused the formation of an antibody capable of reacting with the isolated lipoids *in vitro*. (Of course, an antibody to the protein of pig's serum develops also.) It is noteworthy that the lipid antibody does not develop when lipid and serum are injected simultaneously but at separate sites also horse serum is not an effective substitute for pig's serum for the purpose of developing the lipid antibody (Heimann). Following upon this Sachs Klopstock and Weil demonstrated that rabbits will develop an antibody to their own tissue lipoids when injected with a mixture of alcoholic extract of rabbit kidney and pig's serum. Antisera which react with cholesterol *in vitro* have been obtained similarly a colloidal solution of cholesterol being employed along with pig's serum as the antigen. It would appear that in these reactions the lipoids are not mere indicators. Other example of substances apparently protein-free which react with specific antibodies are the "residues" of Zinsler and Parker and similarly the complex carbohydrates of pneumococci (Heidelberger and Avery) yeast (Muller and Tomesik) and tubercle bacilli (Landis and Dudley). All of these in high dilutions (for example one in several millions) flocculate *in vitro* with antisera to the corresponding organisms. Admixture with protein apparently cannot be responsible for the reactions observed. Further advance of knowledge in this direction however may prove difficult owing to the fact that none of these substance except possibly cholesterol, is yet obtainable in a chemically pure state.

### Specificity

The nature of specificity is still obscure but in certain cases some insight has been obtained. Anaphylactic experiments of Dakin and Dale indicate that egg albumins of different birds may be distinguished by the order in which the various amino-acids are linked in the albumin molecule. This was ascertained by treating the albumins with alkali and noting which of their constituent amino-acids were rendered optically inactive as a result—that is racemized. It was found that in the case of Lysine and methionine different amino-acids were racemized otherwise the proteins are chemically identical. As Landsteiner and his co-workers following Obermayer and Pick have shown that specificity can be modified by chemical procedures. Further Landsteiner by injecting

into animals protein combined with azo-bodies (which are stated to combine only with the tyrosine or histidine group of protein) has obtained antisera which gave the precipitin reaction with compounds formed by the particular azo-component present in the injected material in combination with apparently any protein substance but not with proteins combined with other azo-compounds. An example in antiserum to the azo-protein derived from metanilic acid plus horse serum precipitated azo-proteins derived from metanilic acid plus rabbit serum or globin gliadin or mucin etc but did not precipitate azo-compounds derived from the same proteins along with the azo her azo-bodies—namely with diazotized *p*-ar anilic acid. The antisera did not precipitate solutions of the azo-bodies when coupled with simple substance—or example tyrosine *m*-oxybenzoic acid or salicylic acid but on the analogy of the zone phenomenon the addition to a solution containing an azo-protein or the homologous azo-component had a specific effect in preventing precipitation by the corresponding antiserum. Thus metanilic acid when added to a solution of azo-protein derived from metanilic acid prevented precipitin formation in the presence of the corresponding antiserum but if instead *p*-ar anilic acid was added no inhibition of precipitation occurred in this case. Accordingly it would appear that here a relatively simple organic substance of known constitution—for example metanilic acid—acts *in vitro* as the receptor.

In connection with the specific properties of antigens it has long been known that different organisms may possess antigens in common. The work of Andrieu, Alkowitz and others on agglutinins is a great importance in showing that certain parts of organisms (for example those of the *Salmonella* group and *Escherichia*) may vary from time to time in culture apparently without change in their antigenic content—at one time one antigenic constituent predominating at another time another. The practical importance of this for serum diagnosis and immunization is obvious (see Bruce White) but it is mentioned here in order to emphasize the view that the existence of antigenic molecule can be judged only from their capacity to lead to antibody formation *in vivo* and to combine with antibodies *in vitro* accordingly differences which are detected by these criteria may have little significance for the biology of the organism. It cannot well be doubted that the organisms present in its identity in spite of varying its antigenic products.

### IMMUNITY AND CHEMOTHERAPEUTIC ACTION

There are certain infections in which the active principle of the tissues are capable of bringing about cure solely with the aid of extraneous chemical substances (chemotherapeutic agents). Such infections—for example that with *T. brucei* in man—are in principle curable by the course of the parasite increasing progressively in the blood and death occurring two or three days after the appearance. Not in the case of *Trypanosoma* the parasite is the administration of a dose of an antiserum of this infection may appear at first to be sufficient to cure the trypanosomes (containing) but the parasites increase in numbers in the blood and a fatal relapse is a result occurring in an untreated animal. The first few days are permanently and the treatment is curable. The effects of events has been observed by using example of the treatment with antitrypanosomal compounds (Brown, Cohen, Hingworth and Gelfand). In the case of a chemotherapeutic agent of this class which was used in the body for a long time the same phenomenon occurred—for example when the animal was treated with trypanosomes thirteen days after the drug had been injected. There seems to be only one satisfactory explanation of such behaviour of the parasites—namely that under the influence of the chemotherapeutic agent a proportion of the trypanosomes are destroyed and in consequence an immunity reaction is established in the remainder of them so be killed. A peculiar feature of the process is the indispensable part played by the drug. In the case the infection with *Trypanosoma* *repentum* runs a

The experimental work of the authors and the results are given in the following table which was published in the Journal of Biological Chemistry.

course comparable with that of a bacterial septicaemia, and in uninfected animals immunity phenomena may not appear among many thousands, unless perhaps in an exceptional individual in the form of a slight prolongation of life. But in larger animals, such as rabbits and guinea-pigs, just as in man, the disease has a prolonged course and there is ample time for immunization processes to occur. Nevertheless, death is the inevitable result in these animals in the absence of the chemical compound.

It is well known that cure of trypanosome infections by means of chemotherapeutic agents is followed by a degree of immunity. This may usually be demonstrated in mice by using a drug which is rapidly excreted, and after a few days re-inoculating the animals with the same strain of parasite as caused the original infection. The evidence of immunity consists, as a rule, in a prolongation of the incubation period before the parasites appear in the blood. A fact of striking importance, however, is that the immunity response following treatment by the same agent may vary markedly in degree with different strains of *T. brucei*. Thus, after curing mice heavily infected with the "Prowazek" strain, complete failure of the second inoculation to develop has been repeatedly met with, even when there was an interval of twenty-two days following the original infection. On the other hand, with the "Feix" strain (Elhlich) complete refractoriness has not been observed. Accordingly, it is clear that wide generalizations are not permissible from strain to strain. When one remembers that probably each individual host produces some degree of modification in the strain, the necessity for caution in drawing comprehensive conclusions becomes obvious.

It is likely that the immunity response developed under the influence of a chemotherapeutic agent may be more intense than can be produced by other means. Thus Kiantz found that mice inoculated with a mixture of *Sp. recurrentis* and *salivarium* developed immunity, as shown by delay of the infection following re-inoculation, and also by the organisms which appeared in the blood having the characters of a relapse strain. On the other hand, when the animals were inoculated with a mixture of immune serum and spirochaetes and were subsequently re-inoculated infection developed promptly, and the parasites had the serological characters of the original strain. Similarly, in experiments in which mice received repeated injections of blood swimming with *T. brucei* (Prowazek strain) or *T. equiperdum* killed by the addition of water, we failed to produce any immunity to re-inoculation. Such observations on the influence of chemotherapeutic agents are of importance in connection with human therapy, especially of an infection like syphilis in which rapid sterilization of the body is probably seldom effected, and in which, accordingly, the conditions are favorable for the development of an immunity response. It still remains to be determined how the processes may be regulated so as to produce the most favorable effect for the host.

Another immunity phenomenon deserving of attention is the suppression of one infection by a second. It is recorded by Metzger that when a general paralytic was inoculated simultaneously, for therapeutic reasons, with malaria and relapsing fever organisms the former infection alone developed. After antimalarial treatment the patient had a typical attack of relapsing fever, during which, for the first time, spirochaetes appeared in the blood. Similarly, another patient was inoculated with relapsing fever, and after the first febrile attack was infected with malaria, when the malarial parasites appeared in the blood the spirochaetes ceased to be found, when the malarial infection was treated the spirochaetes reappeared, although no further febrile attacks occurred.

#### ELHLICH'S RECEPTOR HYPOTHESIS

It is obvious that unsusceptibility to infective agents or their products, which is comprised in the term "immunity," results from many factors. Since both host and parasite are possessed of life and powers of adaptation neither can be regarded as altogether passive at any stage in the processes of infection. Accordingly, the interactions which result in immunity must be highly complex, and only in a few favorable circumstances where certain of

the mechanisms predominate can we hope to obtain a clear insight into the phenomena. Such is the case in antitoxic immunity—for example, to diphtheria or tetanus toxin—and to a less extent in other forms of immunity in which the production of antibodies can be demonstrated—for example, the resistance of an immunized guinea-pig to intraperitoneal inoculation with *V. cholerae*.

The acquisition of immunity without the development of antibodies has been repeatedly insisted on. A recent example is afforded by the hepatitis virus, according to Levaditi and his co-workers and others, required immunity in this case is accompanied by marked lethal action toward the virus on the part of the tissues both *in vivo* and *in vitro*, but the body fluids are practically devoid of bactericidal properties and the serum of an immunized animal does not confer passive immunity. Such instances are of the greatest importance as pointing to some further mechanism of tissue immunity, but at present a satisfactory analysis of the conditions is not possible. However, antibodies in general represent a reaction on the part of the host which is inimical to the activities of pathogenic organisms. Therefore to this extent the production of antibodies indicates the acquisition of immunity. But it must be remembered that titration of the antibodies does not necessarily afford an index of the degree of immunity; for, as has been shown—for example, by Muir and McDevie in the case of a haemolysin—the quantitative action of antibodies *in vitro* and *in vivo* may differ greatly.

Since antibodies are the most usual and obvious indication of immunity their mode of origin has always been an urgent problem. As an outstanding phenomenon of biological reaction also their development merits close study. Of the theories not readily capable of disproof that which requires consideration is Elhlich's. His hypothesis consists of two main points essentially as follows: (1) The antigen combines with certain portions of the protoplasm molecule which he called "receptors," or, in the terminology of organic chemists, "side chains." (2) Over-regeneration of the receptors of the cellular protoplasm follows under suitable conditions when the vitality of the cells is not seriously damaged by combination with the antigen, some of these receptors cease to remain attached to the protoplasm of the cells (sessile), and appear "free" in the blood plasma and there constitute antibodies. The originally wide acceptance of the hypothesis has been succeeded by much adverse criticism. Therefore it is necessary to examine it in the light of well established experimental facts. In the first place, the existence of receptors—that is, portions of the protoplasm molecule capable of combining with foreign substances—rests upon evidence which will scarcely bear any other interpretation. The case of serum-fast trypanosomes appears to be decisive. Elhlich, Röchl, and Gulbisson showed that serum-resistant strains resulted from brief contact of trypanosomes *in vitro* with an antibody-containing serum (derived from animals which had been infected with the trypanosomes and then cured by means of a chemotherapeutic agent, an interval being allowed to elapse after the injection of the drug, so that the latter might be eliminated from the body). The treated trypanosomes when freed from the serum and injected into further animals caused an infection which now failed to respond to injections of the antiserum and which preserved this resistance through many passages. Hence the conclusion is that the antibody has combined with a receptor of the trypanosomes and has led to disappearance of the receptor apparatus. The classical experiment of sensitization of red corpuscles by immune body and the transference of the latter from the sensitized cells to uninfected corpuscles of the same species placed in contact with them (Mun, Morgenroth) also requires for its explanation combination of the antibody with some portion of the red corpuscle stroma (the combination being in this case reversible). Whether the mechanism is regarded as purely chemical or as physico-chemical, it agrees with the receptor conception.

As regards the second part of the hypothesis, which was framed to explain the presence of antibodies in the blood plasma, it has not been possible to extract antibodies from any of the tissues of an immunized animal, and to this extent the identity between antibodies and sessile receptors

has not been demonstrated. Various reasons might account for this theoretically, however, the very delicate experimental method of Dole has indicated that in the guinea pig at least the blood free tissues (intestine muscle) of an amphibious animal are hyper sensitive to the homologous antigen—a result which is consistent with the conception of such receptors.

The relations between immunity and the anaphylactic state are still obscure but a characteristic feature is that both depend upon an immunizing procedure with the same sorts of antigens. The bearing of anaphylactic experiments in which the circulations or organs of different animals are conjoined will not be discussed since the conditions appear to be too complex for satisfactory analysis at present.

In conclusion it may be said that the receptor hypothesis in its essential form has not yet been disproved. Certain phenomena, however, such as those of zones and possibly also the Neisser-Wechsberg experiment for which elaborations of the receptor theory were devised are explained on the basis of the interactions between colloids. It must be remembered that immuno reactions take place in colloidal media and that the presence of colloid can alter profoundly the course of even relatively simple chemical reactions.

## DISCUSSION

Prof. O. R. Marm (Chicago) said that the phenomena underlying immunity consisted in the presence of anti-bodies in the serum and in certain little understood alterations in the tissue cells. The properties of sera had been extensively studied and one of the most interesting recent discoveries was that by Ramon of the flocculation reaction in the case of diphtheria antitoxin. It might now be said that physical changes might result from the interaction of antigen and antibody in the case of all the so-called varieties of immunity. Flocculation, precipitation, agglutination, complement fixation were all

evidently closely related. But proceeding and in some way leading to, the physical change there was the specific union of antigen and antibody which was still the cardinal fact in serum reactions. The union seemed to be rather chemical than physical. The fact established by Obermayer and Pick and by Landsteiner, that the introduction of certain groups such as the azo and nitro into the antigen results in the production of a corresponding specific antibody clearly pointed in this direction. The dissociation of antigen and antibody which had been demonstrated *in vitro* in various cases was also noteworthy and important in relation to the phenomena of antibody production *in vivo*. Any classification of antibodies must be used with caution. It should not be supposed that an antiserum contained a definite number of distinct antibodies but rather that it had a non homogeneous content with overlapping moieties each of which could be recognized by some demonstrable physical reaction. The resulting reaction was thus an indicator of the specific chemical combination. The apparently limited number of antibodies which might be developed in an animal raised the question as to whether they all had representatives in the normal cell protoplasm. It was difficult to suppose that all possible antibodies were thus represented. It seemed almost necessary to suppose that the antigen in some way made an impression, as it were on the cell protoplasm and thus led to alteration in the constituent molecules before then appearing in the serum as antibodies. The fundamental changes in the cells in the process of immunization were demonstrated in various ways notably (1) by the reaction to antigen of an immune animal after antibodies had disappeared from the serum (as compared with a normal animal) (2) by the phenomena of local immunity (3) in a striking manner by the reactions of the tissues of an anaphylactic animal.

Profes or EGGREY L. OPIE (University of Pennsylvania) referred to Dr O'Brien's remark that elucidation of the nature of the tuberculin reaction would lead to the explanation of immunity in tuberculois and aid that hypersusceptibility and resistance seemed to be paradoxical. The intensified inflammatory reaction to foreign protein which was often designated as the Arthus phenomenon might be conveniently produced with crystalline egg albumen which acted as a simple antigen. Injected into the skin of a normal rabbit it caused no local inflammation and promptly appeared in the circulating blood. Injected into a rabbit immunized against it it produced an intense reaction at the site of injection and failed to enter the blood. By means of the precipitin test it might be quantitatively shown that the antigen was almost completely fixed at the site of injection into the skin. This local fixation of the antigen was followed by a severe skin reaction but vital organs were protected and no anaphylactic shock occurred. Similar experiments had helped to explain the relation of antigen to antibody with local and general sensitization. Injection of serum from an immunized animal into a normal animal rendered the latter sensitive to the local action of the antigen manifested by the Arthus phenomenon and to anaphylactic shock when antigen was injected into the blood stream. This process of sensitization might be reversed. Injection of antigen into a normal animal rendered it sensitive to the action of antibody so that if serum from an immunized animal was injected into the skin it caused intense local inflammation or if injected into the blood stream anaphylactic shock. The usual process of sensitization had been reversed but the result was the same. When antibody and antigen met within the tissues a reaction occurred and its nature depended upon the special physiology of the part which was the site of their union. Hence some inflammation occurred in the skin and anaphylactic shock when vital organs were implicated. The reaction on the basis of foreign protein were not chance phenomena but had a fundamental significance in the interpretation of immunity.

Lieut Colonel W F HARVEY CII IMS presented a report by himself and Captun K P K IYENGAR IMS on the rate of requirement, the duration and the restoration of immunity after loss in pigeon preventively.

inoculated against fowl cholera. The conclusions were cautiously applied to the case of man, with a view to maintaining certain themes. The first of these was that, though immunity might be maintained by means of vaccines, estimates of the amount of this immunity were probably too optimistic. What was required now was the separate determination by practitioners, hygienists, and immunologists of the degree of value of vaccines. The lines of research were statistical and experimental, and in both it was essential that some mode of strictly alternate case treatment should be adopted if chance was to be placed upon the experiences of the individual who used any particular treatment on animals or man. The experimental work of the authors related to some 750 pigeons, of which 600 were immunized with vaccine and 150 used as controls. A whole series of doses was invariably employed to make the test of the immunity attained. This was considered to afford a better picture than the usual method of minimum lethal doses and their multiples. The equivalent of an alternate series of cases was included as a control in every testing experiment. Batches of immunized pigeons were taken at intervals to test the rate of development of immunity, its duration, and its rate of loss. Then followed the testing of the remainder to determine whether the original immunity, which was induced by a minimum optimum immunizing dose of vaccine and had been lost, could not be restored by the use of much smaller doses than the original. This was found to be the case. The conclusions reached in regard to man were as follows: (1) Single doses of vaccine could produce immunity, but not of so high a degree as two or three doses. (2) Some immunity appeared within a week of commencement of inoculation. (3) Full immunity was obtained within three weeks of the commencement. (4) The duration of immunity after vaccination was shorter than is generally appreciated. (5) For reinoculation doses might be used which were less than even the smallest dose originally required to confer maximum immunity; the immunity so conferred was as great and lasted as long as, but no longer than, the original.

Professor D. C. MATTHEWSON, F.R.C.V.S. (Edinburgh), said that the difficulty in respect of the use of a living virus for immunization purposes might be met: (1) by inoculating at a time when the virus could not exert its full effect—for example, in epizootic abortion of cattle inoculation was used at least two months before the animal became pregnant, (2) by introducing the virus into a situation where it found itself under conditions of maximum difficulty and remote from the predilection site and the vital centres (in contagious bovine pleuropneumonia, for instance, the living virus was inoculated into the tip of the tail), and (3) by using the blood of a carrier as in bovine proplasmiasis, and controlling the effect of the inoculation by the exhibition of a drug (in this example triphenyl-blue). Nevertheless, the use of a living virus was only permissible in herds where the disease already existed. In the bacillary white diarrhoea of chickens the agglutination test was widely used for the detection of the carrier fowl, but the time which warranted rejection was still a debated point, an adoption of the standard of 1/25, as suggested by Doyle, would certainly increase the number of rejections. Roup had accounted for 5.8 per cent of the fowls subjected to *post-mortem* examination in his laboratory during the past thirteen years.

Dr H. D. WRIGHT (London) stated that the early workers had bequeathed the idea that immunity was largely a matter of antibodies acting with or without the co-operation of the body cells. The modifiable part of the combination was the antibody content of the blood, the cellular activity being more or less passive. This generalization could not be accepted in all cases. His interest had been aroused by two phenomena: rabbits inoculated with killed pneumococci, which had not developed demonstrable antibodies, could deal with virulent pneumococci much more effectively than uninfected animals; secondly, although in endocarditis enhanced antibody activity was found in the blood, the disease regularly terminated fatally. In the first case it was clear that antibodies, as at present recognized, were not necessary to the enhanced resistance.

The ordinary test, however, only detected a large amount of antibody and might entirely miss small amounts. Histologically the mechanism of removal was complicated, but the ultimate object was destruction of the bacteria by phagocytosis, failing this the infecting agent tended to become localized. The serum enabled the animal to deal with the bacteria as it would with inert particles—by aggregation and removal by the reticulo-endothelial cells and the polymorphonuclears. The second example illustrated the persistence of infection, a focus being established on a heart valve and persisting until death occurred. At the same time the general resistance to the organism was increased although the septicæmia persisted. This was because the blood examined had usually come straight from an infective focus without being subjected to the destructive action of the liver and lungs. The bacteria were not actually multiplying in the blood, and, if not continually removed from the focus, would be quickly eliminated. The thick barrier of thrombus on the valve prevented free phagocytosis. The problem of chemotherapy and serotherapy must, then, in large part be the problem of the penetration of the foci, which also might produce toxins of unknown nature. Dr Wright concluded that the fundamental principles of antibacterial immunity lay really in the interactions of antibodies and cells, and that the apparent exceptions must be studied carefully with the assistance of the histologist.

Dr W. H. ANDREWS (Ministry of Agriculture) stated that recent work on foot-and-mouth disease had yielded interesting facts in connection with the questions of local immunity and the importance of the channel of entrance of a virus. Professor Browning had referred to the apparent necessity of killing some of the typhlosums in an animal before an immunity reaction could be induced. Edwards's results with bovine surra supported this conclusion, but it was obviously very difficult to induce a similar reaction in the equine body. In connection with the specificity of antibodies the Brucella group deserved consideration, however difficult it might be to distinguish the corresponding antibodies, there could be no doubt that *B. melitensis* and *B. abortus* differed fundamentally in some physiological characters, and *B. abortus* was almost non-pathogenic for man. There was still much to learn of the relations of diet to disease, but striking evidence was available to demonstrate the influence of the diet of the host, not only on internal parasites, but also on ectoparasites, and on the resistance of the host to drugs. In addition to the successful campaigns against such diseases as cholera and plague there were instances of the application of equally successful measures applied to animal diseases, such as underpest and pleuropneumonia. In many large areas in Africa, and especially in South Africa, certain kinds of domestic animals could hardly exist formerly, but they now flourished there in large numbers, thanks to modern methods of prophylaxis, including measures for the destruction of invertebrate vectors. In connection with the treatment of a single form of helminthiasis (due to *Haemonchus contortus*) the swine of animal life had been really enormous. Prophylaxis must always be adapted to the special features of each case. For example, the virus diseases "horse-sickness" and "blue tongue" were very similar—indeed, almost identical—in many of their characters, and yet fundamentally different in some respects. For "blue tongue" a most efficient vaccine could easily be obtained, whereas for "horse-sickness" it was necessary to use a combined serum-virus method. When comparing medical and veterinary work, in connection with epidemic disease, it should never be forgotten that practically all veterinary work had an economic basis, and the scientifically possible was often economically unsound.

Professor T. J. MACKIE (Edinburgh) said that whatever theoretical obscurities there might be, the achievements of practical immunization constituted the indubitable facts of immunity. The obstacles to further apprehensions lay in lack of knowledge of the offensive mechanism of various micro-organisms and the underlying nature of resistance to these. In the past, analysis of immunity had been

largely the analysis of antibody effects, and, while the study of antibodies had been of unique biological interest, the problem of antibodies had tended to obscure the main question—the nature of resistance apart from antitoxin, and in certain instances bacteriolysis it was difficult to believe that antibodies constituted the mechanism of acquired immunity. Antibodies would appear to be only the manifest result of the reaction of the tissues to foreign proteins. In few instances could natural immunity be attributed to antibodies. The two states, natural and acquired immunity, might represent the same biological adaptation. The study of antibodies had revealed the most extraordinary anomalies—for example, the “natural antibodies” which seemed to occur without biological rhyme or reason. Antibody effects could be paralleled by agents which had no relationship to immunity. Haemolytic immune-bodies might be replaced by colloidal stannic acid. Pronounced complement fixation occurred as a result of the interaction between certain animal sera and such agents as dilute alcohol, peptone, amino-acids, cholesterol suspensions, watery extracts of tissue and the lipid suspensions used in the Wassermann test, substances which were not antigenic in the immunological sense. On the other hand phagocytosis constituted an undoubted mechanism of resistance but antimicrobial resistance must be a dual—or perhaps plural—mechanism not only was the parasite disposed of like other foreign bodies, but its toxic products must be inactivated. It might be supposed that bacteria, deprived of their toxins, were like inert foreign bodies, and became an easy prey to phagocytes. It was well known that serum principles rendered bacteria susceptible to phagocytosis; these so-called opsonins might be antitoxic or detoxifying principles. Thus the essential feature of immunity might be the function of tolerance—using the term in its widest sense—to the toxic products of microorganisms. In some cases this tolerance was due to a

specific serum antitoxin, in other a similar principle might remain concerned from immunological analysis as a simple product of the tissues. Until more was known of the intrinsic reactions of cells to poisonous agents the nature of tissue tolerance must remain obscure. It had always appeared remarkable that, while a serum antitoxin was developed in response to exotoxin the opposed endotoxins produced, as a rule, no such response and that, while the exotoxins reproduced experimentally the acute disease associated with the natural infection, the endotoxins produced no specific effects. This raised the question as to whether the antitoxin preparation constituted the essential offensive agency of the organisms from which they were obtained. In the case of certain organisms the true toxin might not be formed in culture and, if immunity to such organisms was antitoxic, present methods of analysis would fail to demonstrate the existence of such defensive agency. On this hypothesis it would be difficult to explain the facts of antityphoid immunity where immunization with dead cultures produced a solid immunity. It was conceivable that a specific toxin was formed in culture but owing to instability was unrecognizable in the usual preparations, and yet on the analogy of toxoid was capable of inciting antitoxin production. Immunity in such cases might in reality be antitoxic, though antitoxin was undemonstrable by present method. The researches of Besredka and his co-workers had shown that a purely tissue resistance might be acquired and that a solid immunity might occur in the absence of recognizable micro-organisms and their toxins; it is probable that antibodies. By the further study of local tissue antagonism a better understanding of immunity would be reached and the great desideratum at the present time was a more exact knowledge of the toxic mechanism of the organisms which failed to produce in culture a specific diffusible toxin.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL

#### DESENSITIZATION BY PEPTONE BEFORE LAPAROTOMY

A series of cases of pneumonia after operation in the hospital at Mel on Monray some few years back set one thinking about the probable cause of this condition.

The cases followed abdominal sections, especially those involving the upper abdomen as is usually observed to be the case. Is it not thought that excessive handling of the bowel will predispose to this sequel of laparotomies and if this be so what is the relation between this act and the onset of a lung condition?

Seeking among the case of ordinary medical practice for lung conditions of sudden onset not probably, due to microbial infections of the respiratory system one notices asthma, acute pulmonary oedema and massive lung collapse. Might not the pneumonia which follows these operations be initiated by a lung change brought about by an influence similar to that which occurs in these medical cases. These cases are probably anaphylactic in origin and the protein shock comes from the intestine.

It occurred to me therefore, that it would be wise to try the effect of desensitizing patients with peptone before the operation. To this end I gave 0.3 gram of peptone in 2 c.c. of normal saline fourteen hours before the anæsthetic was given. The results were so encouraging that we have now adopted this treatment in all abdominal sections in which there is time for such preparation as a routine in our practice. No case which has had peptone has developed pneumonia. There has been no other change in our methods.

I venture to make this preliminary report in case any other hospital may care to try this method.

MONTAGU DIXON, M.D. B.Sc. Lond.,  
Honorary Medical Officer, War Memorial Hospital  
Mel on Monray.

#### UNUSUAL DEVELOPMENTAL ABNORMALITIES

The combination of the two developmental abnormalities observed in the following case is uncommon.

I was called by a midwife to see an infant which was not normal. The mother was a healthy woman of 35 years. By her first husband she had three normal daughters, no miscarriages. This was her first pregnancy after her second marriage also her first male child. The abnormality proved to be epispadias. The penis was represented solely by the glans, a flat, not organ about the size of the tip of an inch across, grooved upon its upper surface. The groove led back into the urethral orifice which was of conoid shape, the from which the urethra passed backward. The glans could be pulled downward a little but normally tended to close the urethral orifice. A certain small amount of corpora cavernosa peria could be felt beneath the skin of the scrotum below the glans. The scrotum was well developed and contained two testicles, appeared normal. The anus was absent and in its place was a small depression from the urethral orifice. There was a small depression in the skin but there was no bulging then or later to suggest that the rectum was anywhere near.

During the following day the infant had several attacks of cyanosis, but no cardiac abnormality was revealed by auscultation limited for sixteen days. During the first four days a paucity of faecal matter by the urethra on two occasions. Thereafter there was no faecal discharge. Micturition appeared to be normal.

The epispadias was of the degree most frequently met with. As far as could be ascertained the urethra passed below the pubic symphysis. The rectal condition can only be guessed at. The most likely explanation of the condition was by passing into the urethra at the lower end of the verumontanum immediately below the opening of the vas deferens although it may have ended on the side along the urethra or the bladder. The prostatic invagination was definite but slight.

The mother raised the question of treatment. The immediate operative procedure would have been the production of an artificial anus by means of colostomy. I was quite certain that the bowel was too far from the perineum to be brought down without a large and tedious operation probably involving both perineal and abdominal approach. If the child survived the operation of colostomy it would be left with incontinence of urine and incontinence of faeces, the latter occurring at a stage when the urethra. This would make infection of the bladder and

so the kidneys, fairly certain, and lead to an early death from pyelitis or some such cause.

With either of the deformities alone the baby might have survived—many persons having undergone colostomy enjoy good health, and I have seen a man of 33 with epispadias, the urethral orifice being among the pubic hair, suffering with his first attack of pyelitis—but the two deformities together were incompatible with life.

The attacks of cyanosis make it probable that the heart was also maldeveloped. No treatment was attempted, and the infant died of obstruction of the bowel. During the last few days the distension of the abdomen was so great that it appeared to be about to burst, over it coiled many distended veins. After death the contents of the stomach ran from the mouth. No post-mortem examination was made.

#### APPARENT INFECTIVITY OF CANCER

The following cases appear to be somewhat similar to those reported by Dr J. MacLeod (October 1st, p. 594).

A married woman, aged 52, first consulted me in February, 1924, complaining of metrorrhagia of three months' duration. She was found to be suffering from inoperable cancer of the cervix. A portion was removed and when submitted to microscopic examination was found to be of the squamous type. She died in August, 1927. Three months after she first saw me her husband (aged 53) came to me. I found him to be suffering from cancer of the glans penis of nine months' duration. He was operated upon and the penis amputated. The growth was found to be a squamous epithelioma. He is still living, and there has been no recurrence in the wound or glands. The husband informed me that sexual intercourse had been continued until about six months before his wife came to see me. At the same time, he stated that he had had the sore on his penis for over a year previous to his coming to see me.

These cases suggest that the husband may have implanted cancer on to the wife's cervix. On the other hand, the whole incident may be a coincidence.

### British Medical Association.

#### CLINICAL AND SCIENTIFIC PROCEEDINGS

##### CITY DIVISION

A W.F.M. attended general meeting of the City Division of the British Medical Association was held at the Metropolitan Hospital on November 1st, with Dr PHILIP HAMILL in the chair, when Dr W. LANGDON BROWN read a paper on the modern aspects of nephritis.

##### Nephritis

Dr Langdon Brown said that nephritis in general was now recognized as due to some toxic or infective cause. Chill did not cause it, but only exacerbated a chronic lesion already present. "Functional" albuminuria did not predispose to nephritis. If the kidney was overwhelmed by a toxin, as in toxicemic kidney, there was a necrosis affecting the convoluted tubules chiefly, the loops of Henle to a less extent, and the glomeruli not at all. The kidney permitted the escape of proteins, diastase, and perhaps sugar from the blood, but did not retain nitrogen. Death or complete recovery was the rule. If the toxic process was rather less severe, typical acute nephritis resulted, in which the glomeruli shrank. If it was much less severe there was a chronic nephritis in which the interstitial tissue suffered more than the tubules. Even in the most chronic form of interstitial nephritis there was some inflammatory reaction. The general conclusion was that the more intense the infection was the more the secreting epithelium suffered; the more chronic it was the more the vessels were affected. Since the glomeruli were vascular tufts they were specially involved. Generally the toxin reached the kidney by the blood stream. If in addition to the toxin the actual infecting organisms were present in the kidney, as in the multiple emboli of infective endocarditis, a number of foci of small-celled infiltration resulted, each of which started an island of nephritis, constituting focal embolic nephritis. Sometimes, especially after tonsillitis, boils, carbuncles, and staphylococcal infections generally, the perinephric tissue was first involved, a metastatic inflammation which

spread through the lymphatics into the kidney. This was the type of nephritis in which pain in the back was most common. Again, the infection might spread upwards from the lower urinary tract, though here too, as Kenneth Walker had shown, it was mainly, if not exclusively, through the lymphatics of the ureter that the infection reached the kidney. Of late the tendency had been towards a secretory rather than an anatomical classification. This was an advantage, since the anatomical basis could only be decided after death, when the opportunity for treatment had passed. Broadly speaking, apart from substances like alcohol or acetone, which merely diffused through the kidney, the organ might excrete two classes of substances: (1) those which could be of use to the body—water, salt, sugar, bile—and (2) those which were merely waste products—urea and ill-fated nitrogenous bodies. To the former the kidney presented a threshold which had to be passed before the substances began to be excreted, in this way was prevented their drainage out of the body. For the latter no such barrier was needed. In hydræmic nephritis only the excretion of the former group was affected, particularly water and salt. Urea might be normally excreted, and it would not be retained in the blood. Chlorides were retained and oedema was marked, but there was little evidence of cardio-vascular change. In azotæmic nephritis there was a gross failure of the concentrating power of the kidney, and since the great work of the kidney in concentration was seen in relation to nitrogenous waste products, and since also urea was the most abundant of these, there would be not only a fall of this substance in the urine, but a rise of it in the blood. The cardio-vascular changes tended to be very marked. As interstitial changes, which were chiefly associated with azotæmia, proceeded more slowly than the parenchymatous, which were chiefly associated with hydræmia, the development of the former gradually altered the picture, producing mixed types. If there was oedema other than cardiac oedema, together with nitrogen retention, it must be an example of a mixed type. The treatment of each type was then considered, and the causation of renal diopsys was discussed. The mode of action of diuretics, and their limitations in the treatment of nephritis, hot air baths, and decapsulation were briefly considered. The value of von Noorden's fruit juice and sugar diet in nitrogen retention was emphasized, as was the futility of attempts to lower blood pressure directly in this condition. Finally, the significance of the different symptoms of uræmia was detailed.

After a keen discussion the meeting terminated with a hearty vote of thanks to Dr Langdon Brown for his most instructive and interesting paper.

### Reports of Societies.

#### RONTGEN SOCIETY AND BRITISH INSTITUTE OF RADIOLOGY.

##### INAUGURAL MEETING

THE inaugural meeting to celebrate the amalgamation of the Röntgen Society and the British Institute of Radiology, the first part of which, in the shape of Sir Humphry Rolleston's presidential address, was reported in the last issue (p. 951), was continued on November 18th, when a physics meeting was held in the morning and a medical meeting in the afternoon.

##### X-ray and Radium Protection

At the physics meeting, over which Sir WILLIAM BRACE presided, Dr G. W. C. KAYE said that it was estimated that well over one hundred of the earlier workers in x-rays had succumbed to their injuries. Protective measures had now been adopted in many countries, in general following the lines recommended by the Protection Committee in England, which sat under Sir Humphry Rolleston's chairmanship. In at least one country, Austria, they had been given legal force. The National Physical Laboratory, which had tested hospital installations, had found a progressive improvement in the efficiency of the systems adopted and in the protective value of the materials—lead, glass, and

rubber—commonly employed. The adequate ventilation of the x-ray room had an importance second only to protection. Spaciousness was not in itself sufficient, for the high-tension discharges speedily vitiated the air to an extent which called for special ventilating arrangements. Each room should be provided with its own suction fan or fans, each with its own outlet, and with inlets near the floor. The screening and developing rooms should be open to sunlight and fresh air when not in use. Dr Kave concluded by saying that radiology under proper conditions was in fact no more dangerous than any other profession, and it was not to the honour of radiology that even minor casualties should now occur yet within the last few months instances had arisen within his own knowledge of young physicists who had been badly burned while undertaking x-ray spectroscopic investigations.

Dr A. E. BOWLER said that in the radiology department at Manchester the dose that one of the workers constantly employed had received was measured over a long period and was found to be 0.007 of the unit skin dose each working day, no damage had been suffered. Dr L. A. ROWNES, as one who had started x-ray work in 1898 and was still actively engaged in it without having received any injury was of opinion that the damage done to workers was through direct exposure to the beam by the opening of the diaphragm. He believed that he was the first to enclose the x-ray tube completely in a lead box.

Another discussion took place on x-ray measurement. Sir WILLIAM BRIDGE said that the comparison of work from different parts of the world was rendered difficult by the want of a proper standard, he looked forward to the establishment of a definite standard as the result of the forthcoming International Congress of Radiology in Stockholm.

#### *Opaque Substances as an Aid to Diagnosis*

At the medical meeting under the chairmanship of Sir HUMPHRY ROLLSTON, four contributions were made on this subject. Sir JAMES PENNY-SMART referred to the use of opaque injections in the investigation of the central nervous system. He spoke first of the type of lipiodol known as light or ascending lipiodol which contained 11 per cent of iodine in olive oil. He did not regard this as of any great advantage. The oil injection even when it got through was blotchy and irregular. Moreover, iodized oil was semi-permanent and its effects good or bad were so far unknown. One important exception in which the use of ascending lipiodol was justified was in determining the lower level of compression due to a spinal cord tumour but such uses were rare because surgeons regarded determination of the upper level as the more important. Turning to the use of heavier lipiodol he said that the most generally employed method was that of injection through the sacro-coccygeal ligament. The use of lipiodol was of course only an accessary method not a short cut to the diagnosis of spinal compression, nor did it replace ordinary clinical examination.

Sir JOHN THOMSON-WALKER dealt with the radiology of diseases of the urinary system, especially of cases necessitating examination of the renal pelvis and ureter. Pnelography he said, had many applications in the diagnosis of renal disease which he summarized as follows: dilatation of renal pelvis and ureter; demonstration of congenital malformations, localization of renal calices of the kidney; diagnosis of renal growths, investigation of the contractile power of renal pelvis; localization of obscure radiological shadows; and investigation of abdominal tumours. He selected for discussion pnelography as an aid to diagnosis of renal growths in 90 per cent of which haematuria was an early symptom. Although a normal pnelogram was not absolutely conclusive it was strong evidence that no growth was present. Changes in the pnelogram indicative of renal growth were flattening and obliteration of one or more of the renal calices, exaggeration of the cupping and elongation of the neck of the calices, obliteration of a portion of the pelvis, and elongation, attenuation, irregularity and displacement of the pelvis, the renal calices and the ureter. Further the axis of the pelvis might be so altered

as to be transverse or obliquely, and though it might be displaced upwards, downwards, inward or outwards lateral displacement was more significant. The normal pelvis and calices frequently showed variations in structure which might be taken to be growths but which were really normal kidney. Dilatation of one or more calices was not unknown, and the shadow of a dilated calix might be separate from that of a distorted pelvis. In the case of growth on the pelvic outlet causing dilatation of the pelvis the pnelogram would show a hydronephrosis indistinguishable from one in other quarters. The speaker discussed objections to the method developed in Paris under the name of 'pneloscopy' in investigating the renal pelvis, and said that he had evolved a method of *sero* pnelography in which after the first pnelogram, the catheter was withdrawn and a fresh radiogram taken at intervals until the renal pelvis was completely emptied. The first point to decide was the time taken by a normal pelvis to rid itself of its contents after being fully distended. In some cases the pelvis emptied itself rapidly, no shadow being found at the end of two minutes. In other cases without any appearance of abnormality, evacuation was only completed after three to five minutes. The longest time taken by a normal pelvis to empty itself was five minutes or a little over. He discussed various factors apart from pathological conditions which might influence the contractile effort of the pelvis and concluded by saying that *sero*-pnelography was easily applied and resulted in a permanent record but as the method was new it was advisable to study normal as well as abnormal condition.

Dr L. S. T. BUTTELL dealt with chest conditions. In the diagnosis of intrapulmonary disease he injected the lipiodol through the crico-thyroid membrane, after anaesthetizing the skin with 2 per cent novocain and injecting into the trachea 0.5 c.c. or 5 per cent cocaine. He used a somewhat larger needle than that for ordinary hypodermic injections, and in order to prevent the needle breaking as a result of the tenderness of the patient to cough when he was certain that the needle was in the trachea he quickly plunged the piston and at once withdrew the needle. The lipiodol could be injected with an orinary laryngeal syringe. By the old method it was not easy to get it into the trachea without making the patient choke or vomit and generally feel uncomfortable. By his method the time occupied was less than two minutes and the operation was painless. He did not advocate giving more than 14 or 15 c.c. of lipiodol because it tended to get into the smallest tubes so that under the x-rays the appearance was that of an amorphous mass which obscured the picture. The use of lipiodol led to the detection of obstruction, and made it possible to determine whether a tumour was connected with the lung or outside it. The method was particularly useful in the diagnosis of bronchiectasis.

Dr R. A. GIBBONS spoke on the use of opaque substances in gynaecological conditions and also touched on the subject of sterilization by x-rays. What he desired to know was whether, working under standard conditions, a dose could be estimated, taking into consideration the age and any natural idiosyncrasy of the patient which would ensure temporary sterilization. If further, it could be proved that permanent sterilization by x-rays was to be regarded as practicable, efficient and harmless it would go far to deprive opponents of sterilization of one strong argument. He said that in cases of sterility in women it was obvious that no examination of the uterus or tubes was called for until all conditions likely to cause interference with conception had been eliminated. It had been estimated that in about 50 per cent of women who were sterile in spite of curettage the cause would be found in the tubes. His method of examination was to prepare the patient exactly as for enneting, antiseptic douches being given beforehand and the vagina and cervix painted with iodine. He used an opaque solution a mixture of sulphate of barium with a mucilage. The bore of the syringe should be as large as possible relative to the size of the canal and very little pressure should be used in injection. He usually gave the injection in the evening and made the examination next morning.

*Dinner and Exhibition*

The meetings closed with a dinner at the Whitechapel Rooms, over which Sir HUMPHRY ROLLESTON presided, when the health of the amalgamated societies was proposed by Sir FRANK DIXON, the Astronomer Royal. Sir HUMPHRY ROLLESTON said that it was hoped that the united body would do much to guide and stimulate radiology in this country, branches across the Tweed and St George's Channel were a possibility, as also sections for special subjects—biology, for example. He read congratulatory letters from Sir Oliver Lodge, Sir J. J. Thomson, and others, and also announced a gift of one hundred guineas from Watson and Sons (Electro-Medical), Limited. The toast of "The Guests" was proposed by Dr C. THURSTAN HOLLAND, and acknowledged by Sir JOHN ROSE BRADFORD and by Mr E. L. RAINER of the National Physical Laboratory.

Concurrently with the meeting an exhibition was held at the Central Hall, Westminster, to which some fourteen firms contributed apparatus and tubes, and half a dozen others photographic material.

## CHRONIC ULCERATION OF THE STOMACH AND DUODENUM

A MEETING of the Manchester Medical Society was held on November 2nd, the president, Dr J. GRAY CROOK, took the chair, and a discussion on chronic gastric and duodenal ulcer was opened by Dr N. KLETZ and Mr A. H. BURGESS.

Dr Kletz said there had been no definite advance in knowledge as regards the etiology. The one factor which seemed to have been established by experience was infection—namely, septic material carried from foci of latent infection and primary emboli in end-arteries of the stomach or duodenum. It was important to continue seeking for the causes, because in the absence of such knowledge all treatment, whether medical or surgical, was liable to fail owing to the cause remaining operative and consequently tending to reproduce the lesion. The diagnosis involved recognition of the presence of an ulcer and also its size, extent, localization, relation to surrounding points and, if possible, its chronicity. Pain was the chief symptom, and its regular rhythmicity had been stated to point to the presence of ulcer and even to indicate, according to the type of rhythm, the position of the lesion, whether gastric or duodenal. Such statements were unwarranted. Gastric pain—namely, pure visceral pain—was either "delayed" or "immediate." The mechanism of production of both these types of pain was considered, and the pain was shown to arise, not in the ulcer itself, but as a result of hypertonus or abnormal tension of gastric musculature. Either pain might be associated with ulcer, but might equally well be evoked by stimuli from distant organs such as the gall bladder and appendix, and act on the stomach through reflex nervous mechanisms. Fullness might have the same significance as pain, and the absence of the pain was no contraindication to the presence of an organic gastric or duodenal lesion. Somatic signs when definitely localized and clearly cut were of great value. A complete investigation was essential, including radiological examination, fractional gastric analysis, and testing the stools for occult blood. The value of each method was considered, and emphasis was laid on the importance of regarding each as one step in the whole, to be correlated accurately with a carefully recorded clinical history and a thorough physical examination. Treatment was by no means necessarily surgical. The first step should always be to seek carefully more chronic foci of infection and deal with it. Especial mention was made of the glow attached to the radiological examination of involved General sinuses and teeth. Cases should be blood sterilized. Operative treatment should always be infecting organism when there was any organic obstruction multiple emboli of innervation, (2) where there was relapse after of small-celled infiltrations, (3) if a penetrating ulcer was an island of epithelium, here was recurrent haemorrhage or Sometimes, and staphylococcus, and induration, and (6) in unfavourable conditions. Other patients should and this applied invariably also to principles and methods of medical

treatment were outlined and the duration of the various phases of treatment indicated. Mention was made of the failure to reduce acidity which might follow gastro-enterostomy and lead to recurrence of symptoms or even to jejunal ulcer. The value of fractional gastric analysis in indicating the secretory type of the stomach was mentioned. Failure was more likely to occur in the hypertonic, rapidly emptying stomach with a rapidly rising curve of acid. Emphasis was laid upon the importance of securing adequate dietetic and medical control after operation, and a plea was put forward for greater co-operation between physician and surgeon in the treatment of the common and troublesome condition of chronic peptic ulcer.

Mr A. H. BURGESS, discussing the statistics of the relative incidence of gastric and duodenal ulcer, said that from the published figures duodenal ulcer appeared to be much commoner than gastric ulcer in the north of England, whereas in London gastric ulcer was more common than duodenal. He referred also to the frequency of coincident gastric and duodenal ulcer. WILKIE (JOURNAL, September 11th, 1926, p. 469), in an analysis of 300 operations, had found that in 16 per cent of all duodenal ulcers there was also a gastric ulcer, and that in 53 per cent, of cases with gastric ulcer one or more duodenal ulcers were present. The work of ROSENOW on the special selective affinity of certain strains of streptococci for certain tissues was mentioned, he had isolated streptococci from the teeth and tonsils of patients with peptic ulcers, and also from ulcers removed by operation, and by the intravenous injection of these streptococci into animals had produced ulcers in their stomachs similar to those in man. From these ulcers streptococci were again isolated, and again produced similar ulcers on intravenous reinjection. These researches emphasized the importance of a careful search for any focus of infection in the teeth, tonsils, nasal sinuses, or elsewhere before operation, and in the appendix and gall bladder during operation. The relation of carcinoma to gastric ulcer was mentioned, and it was considered that the superimposition of carcinoma upon gastric ulcer did not occur in more than from 5 to 10 per cent of cases. Chronic ulcers arose as an acute ulcer or erosion, most of these erosions healed under medical treatment, and only a small proportion became chronic. Medical treatment should, therefore, be adopted in the early stages, and only where it failed to relieve the symptoms, or the symptoms repeatedly recurred, should surgical treatment be considered. Complications, such as haemorrhage, obstruction, subacute or chronic perforation, were indications for surgery. Where a radiological examination showed a definite ulcer crater, or marked deformity of the stomach or of the duodenal cap, operative treatment should be seriously considered. Recalling briefly the history of the operative treatment of gastric or duodenal ulcers, Mr Burgess said that gastro-enterostomy for chronic ulcer of the stomach was first performed by Doyen in 1892, and for duodenal ulcer by Codrill in 1893, for many years afterwards it was the only operative procedure adopted in these cases. It soon became apparent that its results, both immediate and remote, were much better in duodenal than in gastric ulcer. Excision of the gastric ulcer with gastro-enterostomy was tried, but was soon abandoned, since recurring ulcer, and even perforation, occurred. It had now come to be recognized that so far as the surgical treatment of gastric ulcer was concerned there were two essentials: first, the removal of the ulcer itself, either by excision or by the crutery (Balfour), secondly, the performance of a gastro-enterostomy, or, at any rate, of some other means of allowing the bile and pancreatic juice to enter the stomach freely and so diminish the tendency to hyperacidity. The mode of action of gastro-enterostomy was considered both in its mechanical and in its physiological aspects, and it was decided that both of these factors were concerned. If hyperacidity persisted after gastro-enterostomy then a secondary (anastomotic) ulcer was more likely to follow. The two essentials referred to previously could be either separate procedures, as when excision or crutery destruction was combined with gastro-enterostomy, or they might be combined in the single operation of partial gastrectomy, which was often technically easier. The objection to partial gastrectomy was that

it involved the sacrifice of a large amount of healthy stomach often many times greater than the actual ulcer, though in many this did not appear to cause any ill effect, yet several cases of pernicious anemia had been reported as following partial gastrectomy. The most difficult cases were those of ulcers of the lesser curvature high up, near the cardiac orifice. To treat such cases by partial gastrectomy would involve the loss of almost the whole stomach, local excision combined with gastro-enterostomy, if at all possible was the better procedure. Jejunostomy had sometimes to be performed in these cases, absolute rest being given to the stomach for many months, but relapses might occur when mouth feeding is recommenced. Braithwaite had advocated in such cases the operation of cholecyst-gastrostomy ("gastric biliary fistula"), which had been previously suggested by Babcock. In duodenal ulcer gastro-enterostomy gave good results in from 85 to 90 per cent of cases and, combined with the removal of the ulcer by excision or cautery, would appear to be the procedure of choice. The objection was, however, the occasional suppurative jejunal or gastro-jejunal (anastomotic) ulcer. The estimated frequency of this unfortunate complication varied with different writers. Balfour had found that it occurred in 16 per cent of gastro-enterostomies performed at the Mayo Clinic while Leviolin of Mount Sinai Hospital New York had reported that 34 per cent of 68 cases re-examined four to nine years after gastro-enterostomy showed gastro-jejunal ulcer. To avoid this complication surgeons had worked along two lines: some confined themselves to operations on the pyloric region such as pyloroplasty and its many modifications, Finney's operation, or gastro-duodenostomy, while others performed radical excisions of a segment of the duodenum, sometimes combined with extensive resection of the pyloric portion of the stomach (Pannett von Haberer, and Finsterer). One of the main objects of these extensive resections was to produce marked lowering of the gastric acidity but secondary ulceration had been known to follow all of these procedures. Of 100 cases of gastro-jejunal ulcer operated upon at the Mayo Clinic, and analysed by Balfour (Annals of Surgery 1926 [LXXIV, p. 271]) 20 per cent were associated with anastomosis so that diminished acidity after gastro-enterostomy was not a certain protection against gastro-jejunal ulcer.

### ANTERIOR POLIOMYELITIS

At the meeting of the Harveian Society at Paddington Town Hall on November 17th, with Dr E. L. PAXTON the president in the chair, two papers were read on the etiology and treatment of anterior poliomyelitis.

Dr S. A. KENNEDY WILSON said that the practitioner confronted with a case of this disease should be particularly wary in foretelling its course. Nothing could be deduced from the type of case as to whether the attack would be mild or severe. The ordinary textbook description of poliomyelitis as an affliction of the earliest years of life while no doubt substantially true had many exceptions and it was essential that this should always be borne in mind. From the literature of the subject he had been able to discover one case in which this disease appeared in a man aged 67, the earliest age quoted in literature was 12 days and intra-uterine infection was a possibility. Poliomyelitis might be expected at any time of the year although there was a greater incidence in the autumn months. It was difficult to produce poliomyelitis in the experimental animal except in monkeys and not all genera of monkeys were susceptible. The possibility of infection from horses, chickens, and other animals could be largely discounted also from lice and insect vermin it was doubtful whether the virus could be conveyed by inanimate objects. Water and various foods had been examined from time to time with negative results but milk appeared to be incriminated in one instance, where eight cases of poliomyelitis occurred in a small town in New York State and were traced through the milk supply to a person who while in the acute stage of the disease had milked the cows. The speaker thought it highly problematical whether chronic carriers existed. Poliomyelitis did not spread widely. A patient might be infective when he was in the pre-paralytic stage, after

the actual paralysis had declared itself he was much less likely to be so. Turning to therapeutics Dr Wilson instanced the difficulties in the way of specific treatment. It was very difficult to isolate a strain which was not so strong as to kill the experimental monkey or alternatively, not so weak as to fail to produce the disease in the monkey at all, specific treatment here, therefore, had not advanced. Urotropine was in vogue for the treatment of the disease, but, in his own hands, in the large doses advocated, it had proved disappointing and in moderate dose the results were not impressive. Bordier had recorded 65 cases of poliomyelitis treated by x-rays, with appropriate screens, three applications following one another quickly, after which there was a rest interval of twenty days. The speaker had had no experience of the method, but he thought it might be tried.

Dr JAMES COLLIER stated that although poliomyelitis was not supposed to have a family incidence it did sometimes occur in families, and he instanced one case in which four children of one mother were attacked, the infection was said to be purely human in origin. He thought that Dr Wilson had not attached sufficient importance to the part played by adults as carriers. It seemed likely that the carrier was not infectious for a much longer period than the average duration of the disease though it was true that the virus had been obtained from the respiratory mucous membrane of carriers well into the third week. Careful investigation had brought out one extremely cogent fact—namely that a large proportion of patients had never been in the presence of anyone suffering from the disease and therefore could not have been infected directly from another case. As soon as the clinical manifestations of poliomyelitis appeared in the patient he was no longer infectious although he might have been infectious in the incubation period. Lethargic encephalitis also never seemed to be transmitted from a developed case. Poliomyelitis spared boarding schools, institutions and large towns. In epidemics boarding schools enjoyed almost complete immunity. The worst epidemics had almost always been in scattered country communities and there had not been a bad epidemic in a closely populated town. An epidemic appeared to clear out all the susceptibles and to confer some immunity as had been shown by recent epidemics in Kent and the present total absence of cases from those areas. The speaker thought that lumbar puncture might have therapeutic value he was quite certain that it relieved the symptoms and for that reason it should be performed early and repeatedly. He was sure also that hexamine was a prophylactic against infections of the respiratory mucous membrane and that it was wise to give small doses twice or three times a day to members of a household or pupils of a school when there was any infection.

Sir JOHN BROADBENT remarked that he had never seen a case occur in hospital as the result of infection from a patient brought in with poliomyelitis.

Sir WILLIAM WILLCOX agreed about the absence of transference of infection in hospital cases. He had been engaged in hospital practice for thirty years and had seen a number of these cases but not one contracted from an infected patient in hospital (Dr COLLIER interjected that this was not the universal opinion and that there was controversy on this subject). Sir WILLIAM WILLCOX went on to say that at present medical practitioners who were not bacteriologists were rather in a quandary. A few years ago they were satisfied that influenza for instance was caused by the influenza bacillus and typhoid fever by the typhoid bacillus but now ultra microscopical organisms were being incriminated in some diseases. With regard to poliomyelitis he thought it extremely difficult to prove whether a person was a carrier or not and the etiological conditions had not yet been elucidated. He had encountered epidemics of the disease in the small country of Rutland and in 1916 he saw cases in an epidemic in a very much isolated village several miles from a railway station. It was extraordinary how this disease cropped up in isolated places. Some method of treating carrier by disinfection of the respiratory membrane might be tried but remedial should not be advised without some proved scientific basis for their beneficial action.

## Reviews.

### THE OPIUM QUESTION, WITH SPECIAL REFERENCE TO PERSIA

THE author of *The Opium Question, with Special Reference to Persia*,<sup>1</sup> was till lately physician to the British Legation in Teheran, and has spent twenty years in Persia, he writes as a lover and well-wisher of that fascinating country and its people. He deals historically with the opium problem, as well as with the recent efforts of the League of Nations. The poppy was introduced into Persia from Asia Minor or Mesopotamia centuries before the Christian era, but the use of opium for non-medical purposes dates from the tenth century A.D. Its abuse was condemned by Krumpf in his *Amautates Easica* (1712) as "a beastly vice," but opium smoking was not practised until last century, when it was introduced from Central Asia through Khorassan. From 1859 to 1914 the use under poppy cultivation enormously increased, and in the last few years is again increasing. The revenue now amounts to 70,000, and the yield to 600 tons of raw opium per annum. As is the case in India, it is largely used as a "domestic remedy," but about one Persian in ten is an opium smoker, and some of these, especially those who smoke "shirah" or dross, are "physical and moral wrecks." Accepting the League of Nations standard of 12 lb. of opium per 10,000 of the population per annum is that which may be medically or legitimately employed, the figure for Persia is 459 lb. per 10,000. About half the total output of 600 tons is consumed in Persia, the rest is exported, either through Persia into China, or by the Persian Gulf to the Far East. The value of the opium crop amounts to £2,000,000 a year, and 9 per cent. of the Government revenue is derived from this source. It is the most profitable of all crops, and in Isfahan one-fourth of the inhabitants are directly or indirectly engaged in the industry.

As regards the attitude of Persia towards the efforts made by the Hague Opium Convention of 1912, and more recently by the League of Nations, to secure international control of the commerce in dangerous drugs, Dr. NELIGAN, while approving restriction to medical purposes of opium and its derivatives, points out sympathetically the economic, financial, and social difficulties which impeded the desired progress in a producing country such as Persia.

The September meeting of the Assembly of the League of Nations had before it a report from its Fifth Committee dealing with this problem, together with a report from an expert commission which had visited Persia and made investigations on the spot in regard to the production of and commerce in opium, as well as the financial and other considerations involved in the proposed substitution of other crops for that of the poppy. This report had been considered and criticized by the Persian Government. It contended that the amount of Persian opium used for the manufacture of morphine, heroin, and medicinal opium was less than 1 per cent. of the total so utilized, and that the curtailment of cultivation must be equally applied to all opium-producing countries, as well as to those cultivating the coca plant. Moreover, the Persian Government claims that before it can be asked to substitute cereals and other crops for the poppy it must be accorded fiscal autonomy and freedom in the matter of customs tariffs. Nevertheless, willingness was expressed to reduce, three years hence, by 10 per cent. annually, the amount of poppy cultivation, and after another three years to reconsider the position as regards the cultivators, the trade balance, and the budget, as well as the action taken by other producing countries in reducing their output of narcotics.

As Dr. Neligan points out, Persia signed, with reservations, both the Hague Opium Convention of 1912 and the Geneva Agreement of 1925, but has ratified neither. His interesting booklet serves to show how complex a problem the international control of dangerous drugs becomes when the case of a country like Persia is studied in all its bearings. There opium production and consumption have been long established as an industry highly profitable to

the cultivator, the landlord, and the Government, and one in which a large proportion of the population is involved, while its export trade, both licit and illicit, is very great, and must contribute largely to the non-medical use—that is to say, the abuse—of this potent drug in other countries.

### PLASTIC SURGERY

DR. LYONS HUNT, who was an officer of the Medical Corps of the United States Army during the war, and now resides in New York, has written a book on *Plastic Surgery of the Head, Face, and Neck*.<sup>2</sup> He claims in the preface to it that since the war plastic surgery has become a "dignified specialty." Other important volumes on the subject have been published in America and in France, but we feel justified in saying that in comprehensiveness and attention to detail this book is in advance of its fore-runners, is might in the circumstances be expected. The author quotes, with approval, the work of Mr. H. D. Gillies, Dr. Leon Dufourmontel, and others, and necessarily gives a good deal of space to the war surgery of the face. The first chapter on the skin contains a number of useful hints for the guidance of surgeons and consideration of the important question of the "grain" of the skin and of Langer's lines of tension, which must be respected in choosing the site and direction of incisions, if disfigurement is to be avoided or minimized. The author condemns the practice of injecting paraffin, which was a good deal in vogue some years ago. He cites many instances of the evil results which have followed upon it in many cases.

Local anaesthesia is recommended for many operations, including those for cleft palate, and the chapter on this subject has been contributed by Dr. Stanley R. Maxeiner, M.D., F.A.C.S. These methods have been more generally used, and for more serious proceedings, in the United States than in this country, and this chapter will repay careful study. Dr. Hunt deals at length with the important subject of grafts and transplants of all kinds, but especially of the skin. The art of plastic surgery seems to be as full of terms of Greek origin as ophthalmology, and they are offered to our notice without etymological apology. We must confess to having had recourse to the dictionary for a translation of "rhinodectomy," which any Hellenist would know to mean excision of wrinkles. This proceeding appears to be of cosmetic value only, but no doubt the postponement of the appearance of old age may be commercially valuable to men as well as to women. The case of apparent rejuvenation illustrated by the author was of male sex.

This is, as already said, a comprehensive work, for it includes chapters on fractures of the jaws, on keloids and burns, and a chapter by Dr. Sinclair Tousey on physiotherapy in superficial surgery of the face, in which electrotherapeutics come largely into question, but in which somewhat oddly the treatment of keloid by oral administration of thiosinamin is recommended. Dr. Tousey's method of treating moles by painless electro-desiccation seems to be useful.

### DIAGNOSIS OF PANCREATIC DISEASE

THE valuable Rogers Prize at the University of London for 1926 was awarded to Dr. ROBERT COOPE, assistant physician to the Royal Southern Hospital, Liverpool, whose essay has now been published under the title *The Diagnosis of Pancreatic Disease*.<sup>3</sup> It is dedicated to Sir Archibald Grimod, Regius Professor of Medicine at Oxford, in acknowledgement of the stimulus and wisdom of his Schorstein Lecture at the London Hospital in 1920. Dr. Coope's essay is all that such an one should be: it begins with an historical summary which shows how recent is any real pathological knowledge of the pancreas, some anatomical and physiological points of importance are then passed in review, the clinical features are indicated, and the methods of diagnosis discussed. Ordinary and radio-

logical examinations are mentioned but the chief interest lies in the account of the tests for function, and here interpolated in the clear descriptions of the methods employed to detect failure of peristaltic function there are modest references to the author's own investigations—for example into the presence of ferments in the faeces and the fecal nitrogen.

That the critical faculty is not wanting is shown in the section entitled "L'oterie" tests with dubious foundations in which a well known and much discussed test for peristaltic is quoted as 'an example of the premature application of diagnostic tests' to clinical work before any sound and reasonable basis has been found for them."

### THE FUNCTION OF THE RENAL PELVIS

Pyelocopy consists in the radioscopic examination of the pelvis and calyces of the kidney rendered visible by the injection of an opaque liquid. Whereas pyelography merely records the anatomical condition of the kidney at the moment of the taking of an x-ray plate, pyelocopy furnishes information as to the emptying of the pelvis its contractile power and the action of its sphincters. In other words whilst pyelography furnishes only anatomical details pyelocopy gives physiological information. In chapter 1 the authors of *La Pyelocope* F. LECHE, BERNARD FEX and PIERRE TRUCHOT give a detailed account of pyelocopy. The initial stages of the examination are the same as for a pyelography. After a therization of the ureter, the pelvis and calyces are filled with a substance opaque to x-rays, preferably a 50 per cent solution of sodium iodide. In order that the eye of the observer may be capable of noting changes in the shadow observed on the screen a necessary preliminary is that he should remain for a period of fifteen minutes in a darkened room. Moreover, special care must be taken not to overdistend the pelvis as this would cause it to pass into a state of spasm and prevent the study of its motile power. The opaque fluid is therefore, injected only until the complete shadow of the pelvis and calyces is obtained the catheter is then removed and the emptying of the pelvis observed. The way in which this occurs is very similar to the emptying of the stomach. The ureter corresponds roughly in its function to the duodenum—that is to say, its contents remain but a short time within it being hurried onwards by rapid peristaltic waves. To that portion of the pelvis which joins the ureter the authors have applied the term 'ureteral bulb' and have drawn a parallel between it and the output of the duodenum. This bulb is kept continuously filled and evacuates its contents at intervals into the ureter in a fashion that closely resembles the emptying of the contents of the output into the adjacent portions of the duodenum. Above and below the ureteral bulb are two sphincters which control its filling and periodic evacuation. The rhythm of its emptying differs somewhat in different cases but generally the interval is from two to five seconds. It is found that in different pathological conditions this rhythm is altered, as is also the total time required for complete emptying of the calyces and pelvis. Normally the pelvis empties at the rate of one cubic centimetre a minute so that about fifteen minutes may be required for total evacuation. In certain cases of acute pyelitis the emptying may be more rapid and in chronic pyelitis especially when this is associated with marked changes in the pelvis emptying is delayed. Sometimes in cases of chronic pyelonephritis the evacuation which at first appears to be normal, stops so that residue remains in the pelvis. This incomplete emptying is especially marked in cases of hydronephrosis in advanced hydronephrosis complete retention may occur.

The authors have illustrated their book by a series of x-ray plates taken at intervals of three or four minutes. The x-ray plates furnish an extremely interesting record of the way in which the kidney is emptied in health and in disease. Especially suggestive are the plates illustrating the early stages of hydronephrosis it is probable that the application of pyelocopy to this condition will furnish the

key to its etiology. The idea that hydronephrosis is of necessity caused by obstruction in the ureter or in the lower portions of the urinary tract has of course long been abandoned, and the theory that a dislocation of the neuromuscular mechanism of the pelvis may act as the initial cause has been put forward. Pyelocopy according to the technique of Leguen, Fex, and Pierre Truchot will enable us to test the value of this theory and will probably result in a complete elucidation of what has hitherto been a urological puzzle. The work under review is therefore a valuable contribution to urological literature and should be read by all those who are interested in this branch of medicine.

### BACTERIOLOGY FOR DENTAL STUDENTS

Mr. ARTHUR BILLELD, in writing his textbook of bacteriology for dental students, has been mindful of the desire of the dental student for a small book which will give him an insight into general bacteriology and a working knowledge of dental bacteriology in particular. We may say at once that he has succeeded to a remarkable degree in a very difficult task.

In the first fourteen chapters the student is taught the common ground of bacteriology, next the salient points in the life history of the most prevalent 'general' bacteria and finally the characters of more specially dental bacteria in a well considered progression from the general to the particular. The last four chapters are devoted to subjects of general interest—examination of the blood, susceptibility and immunity, vaccines and antisera, and special laboratory investigations.

The dental student who reads this book will probably conclude that there is no royal road to knowledge in bacteriology particularly dental bacteriology and will conceive a deep sense of respect and gratitude for those who are working at a most difficult subject. He will note that while in general bacteriology there is a very considerable body of knowledge in his own particular field agreed facts seem hard to discover even when the author states clearly (p. 156) that McIntosh, Warwick, James and Lazarus Barlow have shown conclusively that *B. acidophilus odontolyticus* Types I and II are the ones engaged in the initial decalcifying process. He contradicts this assertion (p. 139) by quoting Kihara Clarke's recent work on the pathology of caries showing that

*Streptococcus mutans* is the organism responsible for the initial decalcification of the enamel. He may wonder, also whether there is any real meaning in all the antibiotic opsonins and agglutinins which crowd the pages of bacterial therapy, and ask the author who is more than usually clear in his diction when dealing with the subject—on page 199 is it the closely allied organisms that are agglutinated to that causing the infection. Indeed, our chief adverse criticism is the author's slipshod use of English, which is a serious blemish in an otherwise admirable book.

We may suggest that a notice of Drew's work on mouth amoebae and bacteria, and a description of the gum method of section preparation are worth inclusion in a future edition and we may ask for more consistent notes on the pathogenesis of each organism described. All told however we congratulate the author on a work which must have cost many years of hard labour.

### LIFE IN THE POYAI NAVY

When an accomplished writer who has been on up and down the service sets out to write his recollections, one naturally expects some thing more worth reading than usual. In *Reminiscences of a Naval Surgeon* by Surgeon Rear Admiral T. T. JR. C.M.C. and the late Vice-Roy, the author can scarcely fail to find a subject of the greatest interest. The glamour of the sea and the life of a well kept diary recording a varied experience in all parts of the world is a staunch lure for the greatest of fighting services the Royal Navy with the

 36 Text B. L. of E. J. T. D. C. M. C. and the late Vice-Roy. Billeld (Medical Press) Ltd. 15 (Dorset St. W. 1) 1927. 15s. 6d. (P. 15s. 6d.)

consequent advantage of a universal popularity with all ranks and ratings—what better materials could be found for the making of a real life story? Dr Jeans gives it to us on every page, and there is never a dull line throughout his absorbing book. Entering the service in the years before "Channel groping" became the routine life for the majority of officers, he was fortunate in seeing active service at Manila during the Spanish-American war and in South Africa with the Naval Brigade before Pretorius and Bloemfontein. He has the happy knack of expressing himself in a lively and humorous style which adds salt to his vivid descriptions of such scenes as Cronje's larger immediate after the surrender, or the extraordinary state of affairs at Manila after Dewey's much trumpeted "victory" over the Spaniards. About the latter he writes somewhat superstitiously. Later on Dr Jeans served in the flagship on the North American and West Indies station. Stirring relations with Venezuela gave him the opportunity for obtaining first-hand information about that country and its inhabitants. The outbreak of the great war found him in the *Swiftsure*, flagship on the East Indies station. Inevitably the ship was sent as one of the covering ships for the landing at Gallipoli—merely the author had been sent temporarily to the flagship *Lurayalus*, so he had even greater opportunities of seeing things and meeting people than he would have had in his own ship. His account of the campaign is full of interesting details. No one who saw the combined operations from a similar angle could find fault either with the relation of events as they occurred or the critical thoughts which they evoked, with the single exception that the lack of co-ordination between the naval and military authorities at and soon after the landing might have been more emphatically set out.

The author has written down many wise reflections upon the state of the navy. He does not approve the tendency towards early marriage among the younger generation of naval officers, and offers a strong criticism of the educational system which denies to the junior executive officer the exercise of independent thought and the opportunity of sharpening his wits against officers not of his own profession. The powers that be might well listen to the advice he offers for overcoming this very serious defect.

Of the disadvantages of the medical branch he speaks feelingly and with candour. The unfathomable methods of Whitehall, the absence of "command" with the growth of seniority in the civilian branches, the unsoundness of wardroom life for elderly non-executive officers, that inevitable clash between the S.O.B.'s and the B.Y.F.'s (the polite version of which may be rendered as the Silly Old Buffers and the Blooming Young Fools), are all faithfully and sympathetically discussed, though no remedy for these ancient sores is offered. Perhaps there is none: the idea of finding any solution of the problem by the entry of short-term temporary medical officers is decisively rejected by Dr Jeans. But, disadvantages or no, the author is in no doubt that if he had to live his life over again he would retrace his steps, and that should be proof enough of the attraction of the service to the right type of man. The book is full of good stories and life-like character sketches. My lords might do no more than circulate it throughout the medical schools: it could scarcely fail to attract recruits.

### NOTES ON BOOKS

A VERY useful little book entitled *Notes on Clinical Laboratory Methods* has been prepared by the Standing Committee on Laboratory Methods in the University of Glasgow, of which Professor J. R. Currie, dean of the faculty of medicine, is the convener. This committee was established to secure uniformity of the laboratory methods employed in clinical teaching in the medical school. The various pathological tests performed in the side room laboratories of hospital wards are briefly and clearly described, and an attempt is made to complete the series by adding certain additional tests, such as Maclean's methods for estimating the blood sugar and the blood urea. The book is of convenient size for the pocket, and blank pages are provided at the end for additional notes. Although intended primarily for the use of medical students

in Glasgow it will probably be found very popular in other medical schools.

In his small book on *Chronic Pulmonary Catarrh* Dr DUNCAN LEYS, the John and Temple Research Fellow in Diseases of Children at St. Thomas's Hospital, is concerned with the common but non-specific pulmonary infections which frequently recur and eventually leave behind varying degrees of fibrosis. This subject has perhaps been somewhat neglected lately, and left out of consideration owing to the attention paid to lesions of determined bacteriology, though Dr H. Batty Shaw had written definitely about these morbid lesions. Dr Leys reviews the history of pulmonary fibrosis, and then deals with the syndrome of non-specific fibrosis of the lungs, drawing attention to the family incidence and Handfield Jones's conception of a "fibroid diathesis." The question of the nature of the infection, especially that of influenzal origin, is discussed and an account is given of the complications, prognosis, and treatment. The chapter on the x-ray appearances is illustrated by four plates. In an appendix, which must have entailed much labour, are given abstracts of a hundred cases the author has observed or traced. There is ample evidence of the author's conscientious industry and literary research into the subject.

Dr LEONARD P. LOCKHART's little book on *Industrial Hygiene* is intended as a help to managers, foremen, forewomen, and the like in improving and maintaining the well-being of the workpeople under their supervision. As medical officer of Messrs Boots Pure Drug Company at Nottingham he has had opportunities of putting his views to the test of practice. He rightly urges the necessity for co-operation by all concerned, and lays stress on the danger of doing for workers what they had better be taught to do for themselves. The headings of the chapters give a good idea of the matter in the book. These are: The hygiene of the factory workshop, and office, personal hygiene, common diseases, their causation and prevention, the causation, prevention, and management of accidents, the young employee, and a concluding chapter in which such subjects as fatigue, monotony, seating, etc., are shortly touched upon. The list of references to accessible authorities will be useful to those readers who wish to pursue the subject further. This book should fulfil its purpose, and we hope that it will be in the hands of many employers and employees also. The illustrations are clear and adequate, and the lessons given are conveyed in simple language.

The autumn number of *Intiquity* contains a very interesting paper by Dr E. Cecil Curwen on prehistoric agriculture in Britain. One of his conclusions is that probably during the later part of the Bronze Age fields came to be tilled with some sort of foot plough making a furrow, and therefore assumed a rectangular shape, formerly they had been irregular. Not everyone knows that this primitive form of plough is still in use in Skye and the Hebrides. It consists of a stout curved handle some five and a half feet long, set at an angle of 120 degrees into a footpiece nearly three feet long shod with a rough iron point. The crofter drives the footpiece obliquely into the ground by means of a double jerk of his foot, and then, by depressing the handle, levers up the sod, turning it over to his left, then he takes a step backwards and repeats the process. An excellent photograph of a crofter so employed forms the frontispiece to this number. Incidentally Dr Curwen gives an explanation of the step markings still to be seen on the slopes of chalk downs in southern England. They may have puzzled some of our country readers, who have probably found it difficult to accept explanations commonly given. They are relics of early terrace cultivation, when, by ploughing, the turf is removed from an area of ground there is a tendency for the exposed soil to travel downhill and to form an accumulation at the lower edge of the plot. Even on a moderate slope this in time produces a very marked bank, called locally a "lynchet" or "balk." The process is a little difficult to understand without the diagrams provided in the paper. The use of the two ox plough, Dr Curwen thinks, spread in the early Iron Age, but the Saxon conquest caused a complete break of continuity, introducing eight ox ploughs and the long narrow strip fields. Another article in the same number, by Mr Alexander O. Curle, is on the Scottish brochs, circular towers of dry stone masonry built in the Iron Age, but still occupied during the Roman invasion of Scotland. The illustrations in this number, as in its predecessors, are excellent.

## SCROTAL CANCER IN COTTON MULE-SPINNERS

THE LATE DR S R WILSON'S LATE OBSERVATIONS

The extracts appended to this note are from the essay for the Tom Jones surgical scholarship, on "Mule-spinners' cancer," by the late Dr S R Wilson, whose tragic death last September was noted in your columns at the time. The report, sent in in 1910, was never published, but its contents were well known in Manchester.

Until Wilson made his original observation this form of scrotal cancer was only known to occur with rare exceptions in chimney-sweeps and tar and paraffin workers, its occurrence in cotton workers had not been recognized. The essay contained a careful consideration of what was then known about scrotal cancer, gave references to literature on the subject, and embodied Wilson's own new observations which have had such marked effects on the Lancashire cotton trade and the compensation of workmen, and are directing research along a line which may help to an understanding of the causation of cancer. Dr Wilson was associated with Mr A H Southam in a paper on the subject published in the *BRITISH MEDICAL JOURNAL* of November 18th, 1922.

Manchester

E M BROCKBANK  
JOHN S B STOFFORD

### EXTRACTS FROM DR S R WILSON'S ESSAY

After mentioning that the common opinion of surgeons in 1867 was that expressed in the current surgical and pathological textbooks to the effect that epithelioma occurs on the scrotum and is met with in chimney sweeps and paraffin workers Dr Wilson wrote:

This was my point of view until in the later part of 1906 I was appointed house surgeon to Mr Wright at the Manchester Royal Infirmary. Whilst in charge of his wards one or two cases of the disease were admitted and to my surprise on questioning the patients I found they were not chimney sweeps but mule spinners.

My observations would seem to show that the statement as to chimney sweeps is entirely fallacious at any rate as regards South Lancashire, for although about forty cases have been collected in no single instance did the patient follow the occupation of chimney sweep on the other hand, over 80 per cent were spinners, most of them belonging to the class of mule spinners.

Epithelioma of the scrotum must still be regarded as a trades disease but so far as South Lancashire is concerned not of chimney sweeps but of cotton workers. In my own series of cases of epithelioma scroti the youngest patient was aged 32 and the eldest 76.

Ages at which the Growth first Made its Appearance	
Between 30 and 35 years	3 cases
35 and 40	5
40 and 45	5
45 and 50	7+3 cases
50 and 55	2 cases
55 and 60	9
60 and 65	2
65 and 70	1 case
70 and 75	1
75 and 80	2 cases

37+3 cases=40

The average age calculated from the whole series was between 51 and 52 years.

A study of these figures suggests that the age incidence of epithelioma of the scrotum is much the same as for other forms of surface cancer such as epithelioma of lip, tongue, oesophagus and penis.

Average Age	
Lip	59.8 years
Tongue	51.9
Oesophagus	59.6
Penis	52.1
Scrotum	51.9

The above figures all based on the record of the Manchester Royal Infirmary show conclusively the close agreement in age incidence between epithelioma of the scrotum and other forms of surface epithelioma.

At the Manchester Royal Infirmary at least 34 cases were admitted between 1902 and 1910 (nine years) an average of about 4 cases a year. During the two years 1909 and 1910 five cases were admitted each year.

The Manchester figures are thus very striking especially when it is remembered that the Registrar General's report for 1895 shows a mortality of 6 or 7 a year from cancer of the scrotum. This increased frequency of the disease in South Lancashire is I shall endeavour to show associated with cotton spinning for although the London increase can be largely explained by the frequency of the disease in chimney sweeps in the Manchester cases not even one patient was a chimney sweep.

The disease is very intimately associated with certain trade and a consideration of such trades may enable us to determine the particular nature of the irritant in each case. The occupations which appear to predispose markedly to the condition are chimney sweeps, tar and paraffin workers and spinners particularly mule spinners. The relation of the two trades of tar and paraffin workers to epithelioma scroti has long been noted. The occupation which accounts for most of the numerous cases met with in this district is that of cotton spinners.

### Occupations of Patients with Epithelioma of Scrotum

Spinners*	25 cases
Labourers†	5
Gasworks labourers	2
Chemical worker	1 case
Ice worker	1
Furniture porter	1

In most cases mule spinners.  
† Two or three cases entered in the list as labourers were subsequently traced and proved to be mule spinners.

As a rule the workman has spent his life at the particular occupation or long periods such as fourteen to twenty years. Thus we see that more than 80 per cent of the cases were spinners chiefly (when details are ascertainable) mule spinners.

It might be thought at first that as spinning is such an important industry in Lancashire the influence of occupation was accidental, that this is not the case considering that the following points will show:

- 1 If the occupation is accidental how is it that epithelioma scroti is about sixty times as common as on the Continent?
- 2 The records of the Manchester Royal Infirmary show that other forms of surface cancer are not common in spinners.
- 3 Spinners only constitute a comparatively small percentage of the total population.
- 4 Mule spinning is at present at any rate a limited branch of spinning.

The question to be considered is whether the occupation of mule spinning results in some chronic irritation of the parts which leads to cancer.

The growth is in nearly all cases situated in the most dependent part of the scrotum on the left side. In many instances itching was an early symptom and led to rubbing and scratching of the part. In one instance the growth formed over a large hernia on the left side which had existed for sixteen years. Several of the workers themselves attributed the condition to nipping or trapping of the testis whilst at work. One patient complained of profuse sweating in this region. The question next to be considered is whether the nature of the irritation in the case of the mule spinner.

The following possibilities were then considered:

- 1 *Urethral*—By this I imply actual irritation of the part by the clothing. The little urethral meatus is a very important part of the scrotum and is liable to irritation by the friction of the garment. The dirt under the garment is being continually rubbed on the mule spinner in contact with the scrotum. The patient frequently complains of profuse sweating of the part.
- 2 *Dust* might imply irritation by dust or lint which is already mentioned or by the cotton or wool which is so prevalent.
- 3 *Grease*—One cotton mill owner gave me to understand that a good deal of grease got out of the looms in the form of a radio-active.

4 *Salt Crystals of Urea*—When the cotton is wet with sweat being spun one would expect to find a large amount of urea in the cotton which the worker wears when at work.

a specific irritant, the workers in flax suffer from eczema, said to be due to oils present in it

5 *Repeated Traumatism* due to the charr or carriage over which the mule spinner works. Several of the patients gave a history of repeated nipping of the parts, but the information obtained from the owners of the mills themselves was very inconsistent

In view of the fact that some definite irritant is probably responsible for the condition it would be interesting to investigate the chief trades which lead to irritation and eczema, as much valuable information might thus be obtained

#### Clinical Course

The majority of observers state that epithelioma of the scrotum most commonly manifests itself as a wart, or a number of warts, on the scrotum

Several warts resulting from the irritation of soot may exist on the scrotum for years, the wart is not necessarily cancerous, but in course of time, as the result of further irritation, it enlarges, and commences to ulcerate, thus forming an epithelioma, but the transition is so gradual and ill defined that it is impossible to say when the innocent merges into the malignant condition. These were the earliest features observed in patients, the bulk of whom were chimney sweeps. The skin of the scrotum showed no special features outside the area involved by the growth itself

The wart in my cases was probably, from the first, an early malignant manifestation, for in most instances ulceration supervened within twelve months, the shortest period which elapsed before ulceration occurred was two months, and the longest four years

Certain other modes of commencement were also noted. Three patients, all spinners, stated that the condition followed nipping or tripping in machinery, one of them attributed it very definitely to nipping by the charr or carriage over which he walked whilst mule spinning

I cannot find any instance of the condition commencing as an inconspicuous nodule or fissure in my series, but, of course, it has to be borne in mind that such an early condition may have preceded that in which an ulcer was first observed

#### Symptoms

Unfortunately, as in other forms of surface epithelioma, no early symptoms are complained of

Pain is very variable, and in many cases it is entirely absent until the late stages of the disease. Two or three patients said that the part itched, whilst a fairly large number complained of pain on movement or walking. In a few instances pain was very severe, it was of a shooting character, and was referred to the thigh. Loss of flesh was only observed as an early manifestation in two cases. Once the stage of ulceration is reached the patient complains of a fairly profuse foul discharge which causes irritation of the surrounding parts. Two patients complained of hæmorrhage from the ulcer, one was suffering from a varicocele of the same side (left), which may have explained the phenomenon

The further progress of the wart shows at first no special features. It gradually enlarges, becomes more prominent, and more indurated at its base, and frequently cracked on the surface. After a few months, sometimes two to three years, the wart begins to ulcerate in the centre and forms a typical epitheliomatous ulcer. Extension, other than enlargement of the glands in the groin, is not common. Occasionally the growth spreads to the tunica vaginalis and thence to the peritoneum, or the testis itself may be invaded and thickening of the spermatic cord ensue. The ulcer sometimes spreads to and invades the root of the penis, and in two cases amputation of that organ had to be performed

Several points of interest occur in connexion with the enlargement of the lymphatic glands. It has been stated that one marked peculiarity about epithelioma of the scrotum is that glandular enlargement is often very long delayed. My own experience is entirely opposed to this. In most cases the glands were noticed to be enlarged within about six months from the time the growth was observed. In two instances the invasion of the glands was delayed for two years, in another for four years, and in one case for several years

The inner group of the horizontal set of superficial inguinal glands in the groin is the first to be enlarged, but involvement of the remainder of the horizontal set and later of the vertical set soon follows, and in one instance excision of the upper part of the internal sphenous vein had to be performed in order that the glands might be satisfactorily removed. As the growth is usually on the left side of the scrotum the glands in the left groin are the first to be affected, but in consequence of the continuity of the superficial lymphatics of the two sides of the scrotum the glands on both sides are ultimately affected. At the same time it must be clearly understood that

ment of the inguinal glands in this disease does not necessarily signify that malignant deposits have occurred, a few epithelial cells will often be found in the outer lymph path immediately beneath the capsule

The further course of the disease is quite typical. The glands become enlarged, hard, matted together, adherent to skin, and finally burst, giving rise to sinuses exuding a very foul discharge. The femoral vessels are frequently exposed and distinctly visible. Death is due to septic absorption or fatal hæmorrhage. Visceral deposits are very rare. In some of my series, however, the testis, colon, and peritoneum were affected

#### THE PRESENT POSITION

In a post-graduate lecture recently delivered at the Manchester Royal Infirmary Dr E M Brockbank, consulting physician to the Fins Cotton Spinners and Doublers' Association and to the British Cotton Growing Association, and a medical referee, sketched the present position

He recalled that the Home Office Departmental Committee on the subject appointed in March, 1925, in its report issued in April, 1926,<sup>1</sup> stated that the evidence it had heard was strongly in favour of scrotal cancer in mule spinners being due to the prolonged action of mineral oils. In December, 1926, Dr James Robertson (M.O.H., Duxen), in a paper read to the Manchester Pathological Society, which was reported, along with the discussion that followed, in our columns at the time (December 18th, 1926, p 1181), advanced the view that friction from the fork of the overalls worn by the mule spinner, caused by a one-sided movement of the body, was a more likely cause of scrotal cancer than oil. Such irritation, repeated several hundred times a day for ten to fifty years, is alone more than likely to cause cancer. Disease, it would appear, rarely occurs in mills on the Continent, in France belts, which will not cause one-sided pull, are worn. In the cotton waste spinning and the worsted spinning industries in which a similar mule is used, the operatives piece with both hands, and the one-sided pull on the overalls is avoided. They work in a much cooler atmosphere and wear more clothes, and are rarely affected with cancer of any part of the skin

Some other points bearing on the oil theory of the causation of epithelioma of the skin are, to my mind, Dr Brockbank continued, important. It never occurs on the feet of workers in a mule room, who are all barefooted. This is a striking fact, for the many visits which I have paid to cotton mills convince me that the feet must be more or less oily from the very first day the operative walks, as a lad, barefooted into the mule room, the floor of which is covered with oil, until the day he leaves it for the last time, perhaps fifty years later. It is exceedingly difficult to get oil out of a garment or boots, and cotton operatives certainly do not wash their feet in hot water daily. The skin of the dorsum of the foot is very much like that of the body generally, and in 1910-12 cancer of the foot caused death in the general population once for every six deaths caused by scrotal cancer. The feet of mule spinners are liable to temporary injury, but not to chronic irritation. If oil causes epithelioma of the arm and face in mule spinners, why does it not cause it on the foot?

Epithelioma of the penis very rarely occurs in mule spinners only once in 241 cases of epithelioma of the skin in the experience of the Federation of Master Cotton Spinners. As the penis lies in front of the scrotum it must come in contact with oil on the trousers before the scrotum does. Cancer in this situation in 1910-12 caused death three times as often in the adult male population as scrotal cancer did. The nature of the skin in the two situations is, of course, different. Oilers, greasers, and engineers in cotton mills, whose overalls are always very oily, do not get scrotal cancer. They wear more underclothes than mule spinners do

But in spite of all this the more frequent occurrence of cancer of the skin in mule room operatives, as compared with other cotton operatives and the general population, in my opinion justifies the conclusion, in our present state of knowledge, that mineral oil does cause, or contribute to the causation of, cancer of the skin in cotton operatives

Experienced medical opinion in Lancashire considers that cases of epithelioma of the skin in older mule spinners may be the natural development of chronic ichthyosis, which often turns cancerous without any contact with mineral oil

No cases of intrathoracic new growths have occurred in mule-room operatives in the experience of the Manchester Royal Infirmary, although such diseases are usually prevalent in this district (Diguid). This suggests that mineral oil, of which there is a considerable amount in the air of the hot mule room, cannot cause cancer by inhalation

The scientific staff of the Manchester Committee on Cancer are endeavouring to isolate the cancer-producing constituent of mineral oils, and are meeting with promising results

## DIATHESIS

In the history of medicine fashions in ideas and treatment are as prominent as those in dress and language in the outside world. It is not without interest to note how a dominant principle gradually loses its influence, becomes dormant, and later may raise its head and again become popular, though perhaps modified by the experience of its previous eclipse. In passing it may occur to the reader that one of the lessons provided by the study of medical history—a pursuit more in favour with those whose years are mounting up and providing them with the philosophy of experience—is to consider *that each fashion whether new or ancient, though not the whole truth, yet contains some basis of importance worthy of permanent consideration.* In the 18th century, before bacteriology focused attention on the seed, importance was mainly laid on the condition of the soil. In discussing the etiology of disease, and constitution and diathesis then played a prominent part in the current explanations of morbid conditions. John Hunter was followed by Thomas Addison, Thomas Laycock, W. H. Walpole and Jonathan Hutchinson in the study of the constitutional factor of man's maladies, and diatheses or special persisting morbid propensities to particular diseases such as the strumous and the gouty were much in vogue. Although the individual's constitution is not necessarily morbid, the term constitutional diseases is now used more commonly than, and is taking the place of, 'diatheses.' With the revelations of bacteriology attention was for a time concentrated almost exclusively on the exogenous factors of disease—bacteria and protozoa—and diathesis and constitution—the endogenous elements—were cast into the shade, if not ridiculed, as being incapable of demonstration on a plate even microscopically. But the pendulum is now swinging back, and the constitutional or endogenous factors in disease have for some time been studied with the help of anthropological and biochemical methods by Kraus in Berlin, George Draper in New York and others among whom the Regius Professor of Medicine at Oxford has been pre-eminent in connexion with the inborn errors of metabolism. Recently as our readers will remember, Dr Arthur Hurst set out in our columns<sup>1</sup> the practical applications of the constitutional factor in disease in an attractive form.

Sir Archibald Garrod in his philosophical Huxley Lecture on Diathesis printed in full in the opening pages of this issue uses the term as meaning much the same, though with not quite such a wide meaning as constitution. He leaves aside the statistical and anthropological method of approach—that formerly employed by Galton and now by Draper in his Constitutional Clinic at the Presbyterian Hospital, New York—and discusses with a wealth of modern instances the experimental method of investigating diathetic disease, pointing out that the experi-

menter is Nature and not man, and that as evolution makes advances the liability to defects correspondingly increases. The hereditary deviations originating in physico-chemical modifications of the complex molecules of the cells have in the past been greatly elucidated by the Huxley lecturer, who now directs attention to the large group of diseases on the borderland between structural and functional anomalies which are characterized by changes not in any one organ or individual structure, but in special tissues such as muscle, as illustrated by myopathies and progressive myo-sitis ossificans, the nervous system, as shown in familial abiotrophies like Friedrich's ataxia, the red blood cells in congenital haemolytic jaundice, and the bones in fragility with blue sclerotics and subsequently osteosclerosis.

Though less obvious clinically than these structural deviations the chemical mutations are probably no less numerous and as plant and animal life may well be regarded as a complex of physical and chemical processes, then importance cannot be neglected. Thus absence of ferments—for example of thrombokinase in haemophilia—and of the enzyme responsible for the formation of melanin in albinism—may cause serious disability. Inborn errors of metabolism may be born less in the absence of some additional factor—thus congenital porphyrinuria in which the skin is sensitized will not produce hydroa vacciniforme if the surface of the body is protected from light. But the evil effects may be delayed, leucopururia long thought to be harmless—is now known to produce ochronosis or blackening of the cartilages at about the age of 30 years, and later osteoarthritis, cystinuria which like gout is graphically described as a tragedy of insolubility, may or may not cause symptoms, the additional factor of *B. coli* infection of the urinary tract being responsible for the formation of calculi. A caution is thrown out against the temptation to be led into adopting the attractive conception of inborn errors of metabolism as a cloak for ignorance. Much remains to be learnt and even about gout in which the lecturer's father Sir Alfred Garrod eighty years ago demonstrated uricaemia, our knowledge is still very imperfect. There can however be little doubt that the influence and importance of hereditary chemical defects as underlying factors in disease will be shown in the future to be much greater than our present data allow us to regard as proved.

In concluding his lecture Sir Archibald Garrod touches on some other points of interest. Thus it may be difficult to draw a hard and fast line between diathesis and idiosyncrasy, the latter includes those striking examples of protein hypersensitiveness which are manifested by skin eruptions such as urticaria, erythema intermitent, hydrarthrosis, and at least some forms of asthma. It might of course be urged that protein hypersensitiveness may be acquired as in anaphylaxis, whereas a diathesis is inborn, but this is a distinction for further consideration. Another point, mentioned by him rather tantalizingly but not pursued, is the condition which is the converse of diathesis—namely the benign mutations and mitigation in increasing the resistance of the individual in the struggle for existence. In the so-called psychophysical panel on which Draper is at work the instability of the nervous system responsible for functional diseases may be inborn or it is so often the case required at any rate apparently. Sir Archibald Garrod's Huxley Lecture, with its scientific and thoughtful tone, will stimulate others to follow his biochemical footsteps to similar achievements.

## ENVIRONMENT AND THE ENGLISHMAN'S FUTURE

TOWARDS the end of the war, when the population was being sifted to provide fresh battalions, the country was shocked to learn how huge a number of the inhabitants were barely fit for a C3 category. The reports of the recruiting boards were used for a long time after the war by every kind of health reformer, though it is not clear that any proper statistical examination of the figures was made. No regard was paid to the increasing longevity of the race, nor to the diminishing mortality from various causes. It is interesting, therefore, to note the results of an investigation made recently by Professor F. G. Parsons. He set himself to discover whether the physical characteristics of the Englishman are altering in an observable and measurable degree, and if so, whether the changes are due to heredity or environment. He gave a preliminary account of the results of his inquiry to the Section of Anthropology of the British Association. He made an examination of some 5,000 children in London County Council schools, and was impressed by their health and beauty, even in some of the poorest districts. He attributes this to the spread of education during the last fifty years. To test whether better conditions have produced a measurable change, Professor Parsons selected three characteristics in adults for investigation—stature, coloration, and head shape—and with the help of friends made a series of observations. It was found that the average height of labourers in the Chilterns was 5 ft 6 in., and of patients in a mixed practice in Kent 5 ft 7 in. If, in making an estimate, the stunted manufacturing population of the Midlands is included, the average height of labourers in this country may not exceed 5 ft 5 in. But in the well-nourished classes it is different. During the last twenty years the average height of students at St. Thomas's Hospital has in no single year risen to 5 ft 10 in. or fallen below 5 ft 9 in. This, Professor Parsons believes, is a higher average than the students of forty years ago would have yielded, the conclusion is that hygiene and better nutrition have done their work, so far as stature in man is concerned. In women of twenty years ago at the School of Medicine for Women the average height was 5 ft 3 in., ten years later the average was slightly over 5 ft 4 in. This year 150 nurses and massage students at St. Thomas's Hospital show an average height of 5 ft 4.9 in. Professor Parsons believes that in the future the average height for all Englishmen will be 5 ft 9 in., and that the average height of the Englishwoman will later on become stabilized at about 5 ft 7 in.

His study of the colour of the hair and eyes has led him to the opinion that the Englishman's colour is becoming lighter, and not darker, as is usually supposed. Comparing his own statistics in some thousands of cases with those of Beddoe in 1860, he is struck by the increase in fineness. As regards the hair there are many possible sources of error. The use of pomatum in the earlier period is one such source of error. But even in the eye records, which are more reliable, the decline in darkness is large enough to be significant. It would appear, therefore, that the Londoner, at all events, is growing fairer under changing conditions. At the same time there is no doubt that popular impressions are, as Professor Parsons admits, different.

In head measurements Professor Parsons pleads for the use of height measurement in addition to length and breadth. He has adopted the method of adding the length, breadth, and height of the skull,

and dividing each dimension by the sum so obtained. The indices thus yielded are, on the average, only 0.006 lower than those obtained by extracting the cube root of the product of the three dimensions and multiplying it by three. An examination of skulls by this system of measurement shows that until the eighteenth century the only skulls with a proportional cranial height of more than 0.260 are those of the Beaker folk and the Hithite people, both belonging to the Alpine race. By the beginning of the nineteenth century the proportion of the head height in English soldiers had become 0.262. In the early part of the twentieth century it had risen to 0.267 in men of the Royal Engineers, measured by Benington, while in patients at St. Thomas's Hospital at the present day it is 0.271—an index also attained by the members of the British Association. In students of St. Thomas's Hospital and undergraduates at Oxford it was found to be 0.272, British anatomists meeting in Dublin in 1898 attained to 0.275, and the staff at University College to 0.278. Professor Parsons can see no signs of heredity or harking back to any known ancestry in the change which is coming over the English head. All the evidence shows that it would be unjustifiable to claim the Beaker folk as our main ancestors. He thinks it only reasonable to suppose that the Englishman of the future will have a very differently proportioned head from that of any of his ancestors, and thus he considers will be due to the gradual effect of improved conditions of life.

Professor Parsons concludes that the tendency is towards an average height of 5 ft 9 in. for men and of 5 ft 6 in. or 5 ft 7 in. for women, that as to colour, the people are now stationary at a stage with 66 per cent. having light eyes and 34 per cent. having dark, that hair colour has not darkened in the last sixty years, and may be becoming lighter, and that the head shows unmistakable signs of increase in proportional height and decrease in proportional length. Consequently British anthropology may lose some of its sentimental attractions, and there may be greater difficulty in determining whether the modern Englishman has more Saxon, Neolithic, Alpine, or Iron Age blood in his veins. He is becoming an individual who could not be formed by any possible combination of these stocks without the aid of external influences. Heredity alone would not, in Professor Parsons's opinion, account for the Englishman of the future, presumably the increase in height is due to better nourishment, and if conditions of better nourishment continue there should be increasing health.

## ASTHMA AND BRONCHITIS

In an annotation published a short time ago (October 22nd, p. 746) the quotation made by the promoters of the Asthma Research Council from the Registrar-General's returns, to the effect that more than 2,000 men, women, and children died from asthma and its kindred diseases, and every year was said to be probably fallacious, and we ventured the opinion that perhaps not more than half a dozen people died on an average in any year from uncomplicated or nervous asthma in England and Wales. It has been suggested to us that our statement was too sweeping, and our attention has been called to a paragraph in the Registrar-General's Statistical Review for England and Wales for 1925. It is there stated that this combination of causes (bronchitis and asthma) came under some suspicion, the doubt being whether two asthmatics were implied. The paragraph continues "Information as to this was obtained for 299 deaths, of which 193 were ascribed to asthma, 100 to bronchitis without asthma, and 6 to

'cardiac asthma.' But the significance of the combination proves to vary with its order, 242 returns of bronchitis, asthma proved to imply asthma in 146 cases or 60 per cent, bronchitis alone in 90 cases, or 37 per cent, and cardiac asthma in 6 cases or 3 per cent, whereas of 57 returns of 'asthma, bronchitis,' 47 proved to be asthma, 57 per cent, and only 10 bronchitis." It need hardly be said that we did not intend to suggest that the fallacy, if there be one, was due to the way in which the statistics were handled in the Registrar General's office and we had not in mind at the time the paragraph quoted above. The special inquiry therein mentioned appears to have been undertaken in order to ascertain whether the term 'bronchitis and asthma' was meant to imply a primarily spasmodic element which would justify the deaths being classed under asthma or whether the combination in practice meant nothing more than bronchitis. The results of the special inquiry seem to lead to the conclusion that the British practitioner, in certifying bronchitis and asthma, means something more than bronchitis, in the large majority of cases the answer to the inquiry was that bronchitis occurred during the course of asthma. One restricted the term 'paroxysmal asthma' to the independent disease but went on to say that in long-standing cases chronic bronchitis and emphysema complicate the disease and later is added hypertrophy of the heart." This addition to the definition certainly suggests that Osler recommended that there is a considerable mortality resulting indirectly from spasmodic asthma, which must be attributed to it as a primary cause under the usual rules of mortality tabulation. The result of the inquiry quoted points to the conclusion that in the case of most of the deaths so certified in this country asthma was thought to be the pre-existing condition. At the same time, we are disposed to adhere to our original statement that uncomplicated spasmodic asthma very rarely causes death and to maintain that bronchitis is one of the more common of the many causes of a series of attacks of asthma, but acts as much only in an individual with the asthmatic constitution. Infection of the nasal sinuses is probably a still more common exciting cause, tonsillitis is another but less common. Both also predispose to bronchitis. Because of these two circumstances bronchitis is often associated with asthma. Bronchitis complicated with asthma has a definitely higher mortality than bronchitis without asthma as the added bronchial spasm throws an additional burden upon the heart. There does not seem to be any good evidence that asthma in itself predisposes to bronchitis but as bronchitis is very common and as both bronchitis and such predisposing causes of bronchitis as sinusitis and tonsillitis are causes of attacks in asthmatic individuals sooner or later a majority of asthmatics have attacks of bronchitis. Thus, whereas hardly any asthmatics die from a single good remedy due from asthma and bronchitis. At the same time we are free to admit that the relation of bronchitis to asthma remains most confusing and therefore hope that the new council's appeal for public subscriptions to the fund it desires to raise for the purpose of defraying the expense of systematic inquiry may be successful. We are glad to know that it has now constituted an Advisory Medical Committee consisting of Dr A. F. Hurst of Guy's Hospital, Mr V. E. Negus, F.R.C.S., of the Throat Department of King's College Hospital, Dr R. J. S. McDowell, professor of physiology at King's College, Dr Gilbert Scott, medical officer to the Radiological Department of the London Hospital, Dr H. W. Barber, physician to the Skin Department Guy's Hospital, Dr R. D. Gillespie, lecturer on psychological medicine at Guy's Hospital, Dr E. C. Dodd, professor of biochemistry at the Middlesex Hospital, and Surgeon Rear Admiral T. T. Jarr, C.M.G., R.N. (ret.) secretary. It is proposed eventually to add a bacteriologist to the committee.

# COUGH AND STOMACH COUGH

THE paper by Professor Gunn on "The action of expectorants" (p. 972) occupies rather an exceptional position amongst the many valuable contributions made at the Annual Meeting, simply because it deals with a subject in which no important advances have recently been made. It is natural that attention should be focused on what may be termed the growing points in medical science, but really it is those regions in which advance has ceased that ought perhaps to receive chief attention. The treatment of cough is one of those unlucky subjects in which progress is slow or even absent, for it has remained practically stationary for half a century, the reason for this certainly is not that it has reached such a stage of perfection that advance is impossible. Professor Gunn has performed the very useful task of summarizing our present knowledge of the subject and of pointing out the chief deficiencies in this knowledge. In the first place, information concerning the normal physiological mechanisms by means of which the bronchial tree cleared of fluid is extremely scanty. We know that the bronchial muscles can contract and relax, and we know numerous reflexes and drugs that produce this effect but we do not know for certain whether peristaltic waves of contraction can pass along the smaller bronchi and thus clear them of fluid. The most important expectorants are included in the group that produces reflex effects in the lungs due to irritation of the gastric mucous membrane. Unfortunately, in this case we have only a vague knowledge of the effects that are thus produced, for instance, we do not know whether the main effect is increase in the bronchial secretion or increase in the activity of the bronchial muscles. The condition known as stomach cough is of interest in this connexion. There is good clinical evidence for its existence, and its occurrence in gastric disorder is to be anticipated from the fact that irritation of the gastric mucous membrane is the easiest method of producing increased expectoration. Very little, however, is known about the causation and treatment of stomach cough, although as Professor Gunn mentions Blunt recognized the condition and, indeed gave a graphic account of the manner in which a patient who was apparently in a highly dangerous condition from exhaustion and partial asphyxia was cured rapidly by the administration of such a simple remedy as sodium bicarbonate. It is unnecessary to point out the seriousness of persistent cough as a complication in disease for the interference with sleep that it causes is alone sufficient to make its efficient treatment a matter of great importance. The fact that modern medicine has made no real advance in methods for the alleviation of cough is a distinct reproach to therapeutics. Unfortunately the problem is one in which animal experiments can give relatively little help and the chief hope would seem to be in the discovery of improved clinical methods for the measurement of the actual effects produced in diseased lungs by the administration of expectorants.

## UNDERFEEDING IN EARLY INFANCY

THE current issue of the *Archives of Disease in Childhood* contains a paper by Dr Donald Paterson and Dr A. Marr-Claudes in which they seek to prove that underfeeding is of frequent occurrence in early infancy. The paper is founded on observations made in the out-patient department of the Hospital for Sick Children, Great Ormond Street and the authors go so far as to say that the vast majority of infants brought to that department suffering from gastric symptoms and failure to gain in weight were really being underfed. A hundred cases were taken from the out-patients under 6 months of age unselected except that

*Archives of Disease in Childhood* is issued by the British Medical Association, 11, St Andrews Place, Cambridge, N. 1. Single copies 6d.

infants with organic disease were excluded, fifty were wholly or partially breast-fed and fifty were artificially fed, all cases were given cod-liver oil emulsion along with their corrected diets. Of the breast-fed twenty-eight were definitely underfed. In each case a test feed was carried out and additional artificial feeds (complementary feeds) given immediately after the breast. Overfeeding on the breast was observed in one case only. This bears out the impression previously formed that overfeeding on the breast very rarely produces severe disturbance. Eight cases were underfed on the breast, but were already having complementary feeds. Augmentation of these complementary feeds produced an average gain of 8 oz. in the first week. The most markedly subnormal cases were instances of rumination, where the infant, usually a female, had formed the habit of regurgitating its food. Dramatic improvement occurred on giving thickened, concentrated feeds. Congenital pyloric stenosis was diagnosed in nine out of these fifty breast-fed infants. Of the fifty infants fed artificially, twenty-seven were receiving an insufficient number of calories, being starved on all three elements—carbohydrate, fat, and protein. Here the infant was left on the food it was having, but this was increased or altered suitably, so that its balance was adjusted. Sixteen of the infants were receiving an insufficient number of calories generally, but especially in carbohydrate, in such cases carbohydrate was added to the diet. In four cases the feed was sufficient in quantity, but carbohydrate was grossly deficient; all were being fed on dried milks without the addition of sugar. In only one case was there floundering, but the infants were very young and were generally underfed. Overfeeding was met with in two cases only, one of them had fat dyspepsia, the other was being grossly overfed, all the elements in the diet being in excess. It will be seen that of the 100 cases examined nine were underfed on account of pyloric stenosis, and four had required a nervous habit of vomiting (ruminations), their starvation was therefore secondary to a functional complaint. Three were overfed, leaving 84 per cent who were definitely receiving an insufficient number of calories. A proportion of the 84 per cent were being starved because the mother had insufficient breast milk, but at least an equal proportion who were artificially fed were getting insufficient quantities. In some cases the mother explained the size of the feed by saying that she had followed the directions on the tin. With one or two exceptions the directions on the tins of dried milks run at feeding infants by age rather than by weight. Thus an infant weighing only five or six pounds was receiving the same quantity as an infant of the same age weighing ten or eleven pounds, regardless of the difference in their caloric requirements. Most full-cream dried milks have no added sugar, and when made up simply reconstitute cow's milk. Thus sugar, the most important element in causing the child to put on weight, is left out. In this series twenty can be accounted for by a lack of sugar in the diet. The authors plead for the revision of the feeding directions on the tins of dried milks, as they believe that much harm results when the present directions are closely followed. From the examination of this series of 100 cases the authors draw the conclusion that the chief cause of gastric symptoms and failure to gain in weight in infants under 6 months attending out-patient departments is that they are receiving an insufficient quantity of food.

#### IMPERIAL CANCER RESEARCH FUND

THE twenty-fifth annual report of the Imperial Cancer Research Fund has now been issued. It may be recalled that a year ago it was decided that annual meetings of the Fund should no longer be held though the publication of the annual report would be continued. Dr. J. A.

Muiry, director of the Fund's laboratory, devotes attention in the present report to the question of the multiplicity of malignant growths, which formed the subject of the *Lancet* Lecture delivered by him at Cambridge last May. He had found that attempts to induce the cancer in mice after the removal of a mammary excision, or of an experimentally produced cancer, failed completely, but adds that other workers have not observed such an inhibition, and some doubt its existence. Further experiments are in progress which, it is hoped, will throw light on these divergent results. Another subject treated in the report is nuclear degeneration following pluripolar mitosis, which the director dealt with in his presidential address to the Royal Microscopical Society in January. Dr. W. Carmichael contributed a popular account of the evolution of cancer research to the April and May issues of the *Nineteenth Century and After*, with a view to providing educated laymen with a general summary of the knowledge that has been gained. Dr. Muiry refers to the visit on behalf of the Fund of Dr. Carmichael and Carlsberg to Berlin during the summer, in order to investigate Professor Warburg's biochemical conception of the nature of cancer. Warburg finds that tumour tissues are able not only to break down carbohydrates by normal respiratory processes, but also, when deprived of oxygen, can act like the yeasts and split carbohydrate so that lactic acid appears as a final product. Tumour tissues can employ both the oxidation and splitting processes, even when the supply of oxygen is not restricted, and thus give evidence of a mode of metabolism which is characteristic, distinguishing them from all normal tissues except the retina. On this basis Warburg has erected a hypothesis of tumour origin from oxygen deficiency. During the financial year ending June 24th, 1927, the Imperial Cancer Research Fund received subscriptions amounting to £2,001, representing a decrease of £578, the sum received from legacies was £1,917, which was less by £32 than that of the previous year. The total receipts were £13,489, and the expenditure £11,996.

#### THE EARLY NOTIFICATION OF TUBERCULOSIS

SIRISACTION with the decline of tuberculosis in this country ought not to obscure the fact that the campaign against this disease is not being pressed in some respects so energetically as is desirable. One of the primary objects of the tuberculosis dispensary has always been the search for patients in the initial stages of the infective process, in order that the saving value of the stretch in time may be practically demonstrated. The first difficulties as regards the provision of sanatorium and other treatment for these patients have been more successfully surmounted than is perhaps generally realized, but much remains to be done with regard to early notification. Thus it has been calculated that only about 20 to 25 per cent of the patients who apply for treatment are in the early and eminently curable stage, and this in spite of the efforts that have been made to educate the community during the last quarter of a century. Statistics relating to London boroughs indicate that in 46 per cent of the deaths due to tuberculosis in 1926, no notification of the disease had been made until within three months of death. It is considered that there must be a very definite improvement in this respect before the eradication of tuberculosis can be accelerated. The conditions that stand in the way of early notification are well known. There is, for example, the insidious onset of the disease and the natural reluctance of many persons to submit to medical examination for symptoms which, it is fondly hoped, are only transient; thus the infection is enabled to get a firm foothold. It is realized, moreover, that the results of such an examination may necessitate the abandonment of work, with consequent

financial anxiety and every doubtful chance of full resumption later, it is only natural that the first step should be put off from month to month. In the absence of tubercle bacilli from the sputum both private practitioners and menbers of hospital staffs are faced with the temptation to ignore other factors in the diagnosis, and to wait until there can be no possible doubt of the nature of the malady. Notification in the minds of some people seems to imply subsequent interference with personal liberty, and is therefore, unpopular, while the kindly and sometimes justifiable impulse to shield the patient from alarm by putting a less grave construction on the symptoms than is strictly permissible may have unhappy sequels in the form of inadequate treatment. The problem is many-sided and difficult, but some conclusions appear possible. There is need of greater enlightenment of the community, and even of medical practitioners, including those attached to hospitals as to the facilities available for the treatment of early cases. The economic difficulty would be greatly lessened if the public could be made to realize that the patient trained in the sanatorium, even though definitely tuberculous, is a far less dangerous companion in the workshop or office than the careless undisciplined man who is shielded by a diagnosis of bronchitis because tubercle bacilli were not discovered in his sputum by a single examination. Such realization would facilitate the re-entry of many treated and instructed patients into active life, and would obviate much unnecessary and uneconomic invalidism. With such a brighter prospect, notification and sanatorium treatment would lose much of their unpopularity with the medical profession and the laity, and would help in the discovery of curable early cases. The fact remains that failure to notify the individual consumptive, however excusable it may seem, amounts practically to a crime against the community. Such notification figures as those recorded above are a danger signal, and call for definite action.

#### A SURGICAL SUPPLY DEPOT

THE work done by the amateur workers of the Kensington Surgical Supply Depot during the war was very useful, but it is perhaps less generally known that the same work has been carried on continuously since the end of the war and its scope widened in various directions. Many of the workers are unpaid for the depot is not managed on a commercial basis and no profit is made. Indeed, but for voluntary contributions its activities would soon come to an end. In order to bring the productions of the depot to the notice of a wider circle of medical men an exhibition was organized in Nottingham Street St Marylebone, on two days last week. The work there shown did great credit to the workers who produced it. Particularly notable for their excellence were the numerous types of appliances made of celluloid a material devised during the war in the experimental workshop of the Ministry of Pensions at Queen Mary's Convalescent Auxiliary Hospital at Roehampton for the construction of artificial limb sockets. In it "Certus" glue which is a remarkably strong adhesive prepared from casein takes the place of the celluloid long used in the preparation of celluloid splints and jackets. Instead of the layers of muslin being impregnated with celluloid, which needs acetone as a solvent they are steeped in a watery mixture of Certus glue. Celluloid is, however, used as a surface finish. Such appliances are light, strong and non-inflammable. An excellent and really artistic artificial hand for a case of amputation near the wrist was shown. Such hands have been largely issued by the Ministry of Pensions and are found to be much lighter and much stronger than the old wooden hand which is now nearly obsolete. All sorts of

appliances in this material, from spinal jackets to talipes splints for babies, were exhibited. The well known fibrous plasters which are of such value in the stages of convalescence after amputation, were to be seen, as well as more ambitious attempts at the production of artificial limbs, some of which at least were evidently successful. There is, indeed, no form of mutilation, defect, or disability for which the depot is unable to offer a light, strong, and practical appliance. Thomas's splints, walking instruments, and high cork boots, all were shown. The metal work in steel and duralumin shows a high degree of technical achievement. A certain number of crippled boys have been trained in the construction of surgical boots. During the last six years work has been done for 193 hospitals, besides numerous private cases. We commend this society to the notice of all practitioners who need appliances for their less well-to-do patients. The annual bazaar in aid of the funds has been fixed for Tuesday and Wednesday, November 29th and 30th at the Kensington Town Hall. The address of the depot is 23 Upper Ladbroke Place, Kensington, W 8.

#### THE REGIUS CHAIR OF MEDICINE AT OXFORD

SIR E. FAIRHUR BIZZARD has been appointed Regius Professor of Medicine in the University of Oxford in succession to Sir Archibald Garrod who is resigning but will, we hope in his retirement make other contributions to medical literature of the value of that which appears in our issue this week. Sir Fairquhar Buzzard, who was born at the end of 1871 was the eldest son of the late Dr Thomas Buzzard, one of the leading neurologists in London of his day. Sir Fairquhar Buzzard was educated at Charterhouse and Magdalen College, Oxford where he graduated M.B., Ch.B. in 1898 and M.D. in 1902. He was a student of St Thomas's Hospital to which he eventually became physician. He was also at one time attached to the staff of the National Hospital for Paralysis, Queen Square and was the joint author, with Dr J. G. Greenfield pathologist to that hospital of a work on the *Pathology of the Nervous System* he has contributed many articles on neurology to the medical press and in 1907 gave the Goulstonian Lectures to the Royal College of Physicians at London on certain acute infective and toxic conditions of the nervous system. He was president of the Section of Neurology and Psychology of the British Medical Association at the Annual Meeting at Nottingham in 1926, and was a member of the Association's Special Committee on Tests for Drunkenness, which recently concluded its labours. He is a representative of the Royal College of Physicians of London on the General Medical Council he is physician extraordinary to the King and received the honour of K.C.V.O. last June. In the nineties he was one of the famous Old Curriehian XI which carried off all the amateur Association football honours.

#### THE ROYAL SOCIETY OF MEDICINE

THE Royal Society of Medicine will hold its first social evening of the present season at 1, Wimpole Street on Wednesday December 14th. Fellows and their friends will be received in the library at 8.30 o'clock by the President and Lady Berry and at 9.30 Sir Alexander Houston, Director of water examinations Metropolitan Water Board, will give an address entitled "The romance of London's water supply." The library will be open and a number of exhibits will be on view. Guests will need invitation card unless accompanied by a Fellow Member or Associate who can obtain cards from the secretary of the society.

## ROYAL SOCIETY OF MEDICINE

## ANNUAL DINNER

THE annual dinner of the Royal Society of Medicine took place on November 14th at the Hotel Victoria, when Sir JAMES BERRY presided over a company of more than three hundred. The principal guests were the Right Hon Lord Darling of Lougham, Sir John Rose Bradford (President, Royal College of Physicians), Sir Berkeley Moynihan, Bt (President, Royal College of Surgeons), Sir Arthur Keith (President, British Association) and the Presidents of all the principal medical societies of London. Another distinguished member of the company was Dr von Puquet, Professor of Children's Diseases, Vienna.

Lord DARLING, in a light and amusing speech, proposed the health of the society, and sketched with some romantic touches the history of the profession from the earliest introduction of medicine into the world by Chiron the centaur down to the formation of the Royal Medical and Chirurgical Society in 1805, and the fusion of that body with seventeen other societies to form the Royal Society of Medicine in 1907. It was not inappropriate, said his lordship, that a lawyer should propose such a toast, seeing that lawyers, especially in the administration of the criminal law, had done much to preserve the privileges of the medical profession. His own earliest recollections were of visits paid to a solemn-looking gentleman, dressed in a frock-coat, with high "choker" round his neck, and shepherd's plaid trousers, who commonly shook his head and appeared greatly to depress his (Lord Darling's) mother. Following upon such visits there arrived at the house a little bottle filled with fluid, generally black, with the invariable instruction that it must be well shaken—an instruction which was misread by the misadvent of one patient, who, instead of shaking the bottle, shook his master. Lord Darling further stated that as a child he took regularly James's powder concealed in jam as well as other medicaments, all this he had suffered in the interests of the medical profession, and he sometimes wondered how many discoveries had been made at his expense. But he bore the profession no ill will, and now that the science of medicine had so manifestly developed, he was tempted to wish that it might be developed still further, and that some therapy might be discovered and entrusted to the profession whereby people might be cured of wrong political opinions.

Sir STCLAIR THOMSON, immediate past-president of the society, then presented the presidential badge, which was the subject of a short description and sketch in our issue of November 12th (p. 890). He said that it had struck him as curious that this great and flourishing society should not have been furnished with the insignia which was usual in kindred institutions, such as the Royal Colleges and the Royal Society. His first effort to remedy the omission was to present a claim of office, which the society accepted from him at the last annual dinner. Next he bethought himself of a badge or jewel to hang to it, and consulted some members of the profession, like Sir D'ARCY POWER, Dr CHARLES SINGER, Mr WALTER SPENCER, and Dr ARNOLD CHAPMAN, who were learned in art and heraldry. A claim of office required a badge, a badge suggested a crest, and a crest entailed a coat of arms. After giving the technical description of the coat of arms, which has already appeared in these columns, Sir Stclair Thomson recited the rather melancholy history of the two supporters, SS COSMOS and DAMIAN. These were Arabian physicians, born in the third century, at Aeger in Cilicia, where there was a temple or school of Aesculapius. As COSMOS and DAMIAN gave their services freely the Greeks christened them *ἀναγύριοι*, meaning "moneyless." They were not only medical practitioners, but became saints, and in so doing had some fearful experiences, for this was the time of the Diocletian persecution. They were thrown into prison and beaten, and, this making no impression on them, they were bound and cast into the sea, here, however, an angel loosed their bonds and the "an ashore." It was true, said the speaker amid laughter, that there was no affidavit or statutory declaration as to this, but then there was no prize—at least no earthly prize—not any advertisement. But in the gallery of ancient and modern art in Florence a beautiful picture by Fra Angelico

might be seen, showing the angel helping them ashore. These martyrs were next bound to the stake, but the fire would not hurt them, they were hung upon crosses and stoned, but the stones rebounded and smote their persecutors, and at last the pro-consul, convinced that they were enchanters, had them beheaded, which ended their career as gratuitous medical practitioners. In the twelfth century their bodies were brought to Italy, and they were canonized. Titian, in a picture commemorating the plague in Venice, depicted these two saints, and they also appeared in mosaics or in painting at Rome, Ravenna, and Siena. But it was from the portraits of them in Florence that Mr Martin Travers, the designer of the society's coat of arms and presidential badge, had, in the language of the Garter herald, "relieved" the coat of arms. The principal founder of the Medici family, born on the fate day of the two saints, was christened Cosmas, and by his command, in 1439, Fra Angelico painted a beautiful altar-piece for the convent of St Marco and nine miniatures depicting the history of the saints. In a small chapel in the Church of Santa Croce at Florence there was a stained-glass window by an unknown artist, showing the saints standing side by side, dressed in scarlet robes with green trimmings, and large red hats, and carrying, the one a pharmacy jar and the other a surgeon's knife. At their feet were the arms of the Medici family, for this great family not only showed that it had sprung from a medical stock, as indicated by the six pills on its shield, but adopted these two medical practitioners as its patron saints. As Arabian physicians skilled in the learning of Greece, as canonized saints in the Roman Church, perpetuated in mosaics, painting, and sculpture by the great artists of Italy, and as patrons of the greatest medical family that ever lived, the Medici of Florence, he trusted their inclusion in the coat of arms of the Royal Society of Medicine would be generally approved. He had great pleasure in making this small offering of the chain, badge, and coat of arms to a society whose chain had had so many distinguished occupants, whose funds had had so many generous donors, and whose welfare had enlisted the labours of so many worthy men.

The device was passed round among the company and was very greatly admired.

Sir JAMES BERRY, after suitably acknowledging Sir Stclair Thomson's gift, spoke of a number of domestic matters. During the year there had been five thousand accessions of books to the library. A recent revision of editorial procedure would allow of the more prompt publication of papers. Last year 250 Fellows were elected—fifty more than in any previous normal year. He thought the society might do more in the way of setting up special scientific committees, which it was empowered to appoint under Article 21 of its charter. One such committee, on the administration of anaesthetics—a matter referred to the society from the Ministry of Health—had done valuable work during the year. The society was still burdened with a debt of £20,000 on its building. He paid a tribute to the retiring senior honorary secretary, Mr Gilling Ball, for his admirable services. Dr Letheby Tidy was his worthy successor, and Dr Tidy's place as junior honorary secretary was filled by Mr E. K. Martin. The society was fortunate also in having an admirable permanent staff, all of whom, from the secretary, Mr Geoffrey Edwards, downwards, worked for the society with a devotion and enthusiasm beyond praise.

Mr WARREN LOW, in a very happy speech, proposed the health of the guests and the kindred societies, and had something apt to say about every one of them. Of Sir Arthur Keith, whose name he coupled with the toast, he said that there was reason for pride in the fact that the reigning President of the British Association should be a member of the medical profession, and that in such an exalted position the profession should be represented so ably.

Sir ARTHUR KEITH, in responding, confessed to a dual personality. It was the President of the British Association who had enjoyed the hospitality of the evening, but the "other gentleman" who rose to make the speech was the humble servant of a proud college. To paraphrase his president he was a poor medical practitioner doomed to

the practice of anatomy. He had always kept his foot within the door of medical practice, however, because he had never been quite sure that some day he might not have to open that door quite wide and step into his own surgery. He proceeded to make a few remarks on the rationality of medicine. The great difficulty in the way of making medicine more strictly a science was that of educating the public. Any such effort would find itself confronted for example with the immense authority which an address in Harley Street inspired, although to the rational mind the name would mean nothing at all, but it does you know. The way in which the doctor drove up to one's door, or the way in which his tailor had sent him out into the world, should be matters of absolute indifference to the rational patient, yet the doctor was apt to be assessed not according to his professional worth, but according to his outward appearance. Every young man or woman entering the medical profession was determined to be a rational practitioner with no jot or tittle of quackery, yet the young practitioner scarcely realized what he was up against, which was nothing less than human nature with its complexity and occasional perversities. Nevertheless headway was being made. In the old days it was the Church that ruled the world, now it was coming to be scientific knowledge. No longer did the village surgeon go up to the rectory and ask whether a certain thing was right to be done, but the village doctor went down the street to the surgery and said, "What do you think? Can I preach this next Sunday?"

## SOCIETY OF MEDICAL OFFICERS OF HEALTH

### ANNUAL DINNER

THE annual dinner of the Society of Medical Officers of Health was held at the Piccadilly Hotel on November 17th. In the absence through illness of the president of the society (Dr. J. M. Wheatley) the chair was taken by Dr. I. H. SELL. The guests included the Right Hon. Neville Chamberlain M.P. (Minister of Health), Lord Eustace Peier (President of the Board of Education), Sir George Newman, Dr. Andrew Balfour, Dr. H. B. Braekenhurst (Chairman of Council of the British Medical Association), and the Dean of Westminster, and a number of medical officers were present from other countries: France, Germany, Hungary, Switzerland, Holland, Sweden, Norway, Czechoslovakia, Yugoslavia, Iceland, the Irish Free State, the United States, and Brazil were all represented at the tables.

Dr. SELL, in submitting the toast of 'The Ministry of Health,' did not think it necessary in such an assembly to describe the birth and the growth of the Ministry, but every medical officer hoped that it would go on progressing and experience no regressive stages. In the eight years during which the Ministry had been in existence there had been five Ministers. Perhaps they moved without reluctance to other positions. But Mr. Chamberlain had scored a 'record' in that he had been in office for three years. All present knew Mr. Chamberlain's qualifications. He took his duties so seriously that recently he had been making excursions into various parts of the country to study local administration on the spot. There was one thing which probably Mr. Chamberlain himself did not know, that it resulted from these visits—namely, that certain local magnates had for the first time visited welfare centres, tuberculosis dispensaries, and other 'fads' of their medical officers.

Mr. NEVILLE CHAMBERLAIN, in responding, said that it gave him the greatest pleasure to be present at that gathering in company with so many fellow workers in the cause of public health. While agreeing that the visits to which the chairman had referred might have produced results of which he was proud, he was bound to confess that he did not know whether more to ponder at the extent and variety of the duties which fell to the public health officials or to admire their skill, resource and ingenuity. It was a remarkable fact that although the medical officers were concerned not so much with the treatment of disease as with its prevention, the public had so well comprehended the value of the work done that in these

days of limitation with regard to the number of rates and taxes no single voice was raised in favour of cutting down the preventive services for which medical officers were responsible. He was glad that an increasing number of local authorities were realizing the advantage of employing whole time officers whose attention was not likely to be distracted by different and perhaps conflicting considerations. It was important, if the best was to be got out of the public health service, that there should be the closest co-operation between the Ministry on the one hand and medical officers on the other, and also between medical officers themselves. It was important also that the relations between the county medical officers and district medical officers should be of the closest possible character. The synchronization of their work and the friendly relations between those two sets of officers should always be in the mind of members of the society. Again, the efforts of local authorities and their staffs could never reach full development unless the public co-operated with them, but it was not reasonable to expect such co-operation unless the public had some understanding of the dangers to be avoided and the purpose of the injunctions laid down in health matters. There was one special way in which medical officers could assist in the education of the public. The Ministry of Health every year asked for a report from medical officers, and for the most part received it—after a time! Up to last month over 130 reports for 1926 had not reached the department. Such reports were not only of great assistance to the public and to the general body of medical officers, but to the Minister himself, because they furnished a true and more vivid picture of the conditions in the various localities than could be obtained in any other way. Mr. Chamberlain thought that more use might be made of the medical officers of health in the work of research, not so much in laboratory research as in the study of the mass of facts in their possession on matters with regard to which up to the present there were no generally agreed conclusions. It seemed to him that in regard to the actual results of vaccination—not only in small pox, but in other diseases—to the diversity of practice in regard to scarlet fever and to several other matters, medical officers had before them a vast unexplored field of investigation and research. By taking these matters into their consideration he believed that medical officers would succeed in adding further laurels to those already won and would still further increase the obligation under which they had placed the whole country.

LORD EUSTACE PEIER, in submitting the health of the society, began by paying a tribute to the admirable way in which it carried out one of its functions—namely, co-operation with the Health Committee or the League of Nations in arranging for visits to this country of medical officers from abroad. No more valuable work could be done in these days than that which drew closer the bonds of international fellowship and aimed to consolidate the work of public health over the whole world. It was with a certain amount of diffidence that he spoke of the work of the Board of Education rather than of the society, but he might be permitted to deal with the main characteristics of medical work in the school. The system of medical inspection in the schools at three periods during school life had been practically completed and the service was now concerned with the development of method of treatment of the defects revealed by such inspection. The treatment of minor ailments had increased from 576,127 cases in 1924 to 665,658 in 1926, of visual defects from 162,917 to 196,672, of nose and throat operations from 34,854 to 68,250, and dental treatment—a part of the service particularly necessary to develop—from 654,365 to 852,517. Such growth in two years indicated that the medical officers of health and the school medical officers were really getting to grips with the cancer remaining to be tackled in the development of the school medical service. The most important feature of the last two years had been the development of orthopaedic work throughout the country. Starting with a few authorities who had orthopaedic sections, in 1926 there were 132, or 47 more than in 1925, while school clinics had increased from 70 to 122. Preventive treatment was capable of expansion in other directions. The number of open air schools now being

provided was noteworthy, and he hoped that preventive treatment might be increasingly extended to what those concerned had been content to call mentally defective children. By early special teaching of such children in the ordinary elementary school it might be possible to prevent the stigma involved in transference to a special school which had about it something of the atmosphere of an institution. The press sometimes spoke of the "vast horde of officials" which the development of public health and school medical work was supposed to bring into being. In the county as a whole the nurses engaged wholly or partly in school work represented one to every 1,000 children in the elementary schools, and of these over 40 per cent were district nurses, not directly employed by the educational authority, over 30 per cent were employed in public health work as well as on school medical work, and less than 20 per cent were on school medical work exclusively. Taking the senior school medical officers and assistant officers, the "horde of officials" amounted to one to every 4,000 children. Only 20 per cent of these officials also were exclusively on school work. The Board of Education was to a very great extent enlisting the services of general practitioners. The efficiency of the present organization, though Mr. Chamberlain and the speaker might take some of the credit for it, was really due to the public health officers and school medical officers of the county.

Dr. SELL responded in a very happy speech. He said that one of the subjects which had engaged the attention of the society during the past year was that of education. As a result of Section 67 of the Public Health Act, 1925, the society had had many requests from members for guidance in connexion with voluntary societies which set themselves out to give education in health matters. A Central Council for Health Education had been formed, one of the functions of which was to advise local authorities and their officers as to the value or otherwise of voluntary societies which set themselves out to educate the public. He thought the most important measure which had been put on the Statute Book in this generation was the measure resulting in systematic medical inspection of school children. Central bodies who adopted centralized methods and divided the country up sometimes gave the local men a disconcerting half-hour. For instance, a letter would be received from the Board of Education pointing out that there were fewer cripples in one's area than there ought to be, or from the Ministry of Health, that the local register of blind people had not sufficient names upon it, or from the Board of Control, that the number of mentally deficient was inadequate, and thus after he had been working to prevent and diminish all these things! In turn did he write and say that the intelligence quotient in his area was far and away above the rest of the country! Nevertheless, he thought all members of the society would agree that it was a pleasure to be met in the way they were when they sought assistance from Government departments and their officials, and they welcomed the increased opportunities for consultation over such things as draft regulations.

The remaining toast was that of "The Guests," proposed by Professor BOSTOCK HILL, and responded to by the DR. of WESTMINSTER and Dr. SIEBERSCHMIDT, director of the Institute of Hygiene, Zurich.

## AN OUTBREAK OF PARATYPHOID B FEVER IN WEST HERTS

THROUGH the courtesy of Dr. H. Hyslop Thomson, county medical officer for Hertford, we are able to give authoritative particulars of the recent outbreak of paratyphoid fever in West Herts.

On November 11th Dr. Thomson was notified that several cases of typhoid fever had occurred in the borough and rural district of Hemel Hempstead. The number of cases, including doubtful cases, which had been notified up to and including that day, was 23, of which 11 were in the borough and 12 in the rural district. The total number notified up to November 18th was 116, of which 63 were in the borough of Hemel Hempstead, 42 in the rural district, and 11 in the rural district of Watford. The first steps taken were to

provide, as far as practicable, adequate hospital accommodation for all cases requiring removal to hospital, and to ascertain and immediately to deal with the source of infection. With regard to hospital accommodation, the ground had previously been prepared by the mayor, and it had been possible to make immediate arrangements with the West Herts Hospital by which, in conjunction with the Isolation Hospital, accommodation became available on November 11th for between 40 and 50 patients. Arrangements were made later with the Watford Isolation Hospital to accommodate up to 30 cases, and the number of cases in these three institutions at the present time is as follows: Hemel Hempstead Isolation Hospital 28, West Herts Hospital 48, Watford Isolation Hospital 20—a total of 96. If further hospital accommodation should become necessary it is proposed to arrange for the admission of patients to the Poor Law institution. All the patients were reported early this week to be doing well.

### Source of Infection

The reports of the sanitary inspectors indicated that all the patients notified had a common milk supply, which pointed to milk as the probable source of infection, and this was confirmed by subsequent reports and investigation. On November 11th Dr. Thomson inspected the premises of a retail milkman who had supplied all the patients with milk. He was warned that no further milk would be allowed to be distributed by him unless it was properly sterilized by raising it to a temperature of 150° F. for thirty minutes, this he did. Further investigation showed that this milk dealer received milk from nine farms, as well as occasional accommodation milk from a company, but as the latter was pasteurized it was ruled out as a source of infection. The number of persons employed by the retail dealer in connexion with the distribution of milk was twelve.

On November 12th the investigation was directed in the following directions: (a) bacteriological examination of the water supply, (b) bacteriological examination of samples of milk from the nine farms, (c) blood tests in the case of those who were chiefly employed in handling the milk at the retailer's, and (d) steps to ascertain whether at any of the nine farms there had been any illness suggestive of paratyphoid B fever, which was the type of fever characteristic of the outbreak.

The results of these investigations were as follows:

(1) Two cases of fever occurred on the retailer's premises, one notified on November 4th and the other on November 17th. (2) The blood tests showed that the retailer himself and five of his roundsmen gave a positive or partially positive Widal reaction. (3) At one farm (X) a case of illness was discovered in a child aged 3½, who subsequently gave a positive reaction. This farm also supplied two houses in the neighbourhood with milk, and in one of these houses two cases of paratyphoid fever occurred.

These results indicate the primary source of infection as the child at farm X, who infected the milk supplied to the retail milkman, and though this induced a secondary source of infection by infecting some of the members of the retailer's family and his staff. At two other farms, at one of which was an ex-soldier who had been in Mesopotamia, samples of blood were taken, but with negative results. Further investigation showed that the outbreak was specially limited to three districts. This distribution would be accounted for by the fact that the milk was not regularly mixed and that some of the roundsmen gave positive Widal reactions.

### Action Taken

In addition to sterilization of the retailer's milk the following action has been taken. The mother and her child aged 3½, from farm X, and the two patients in the retailer's household, were removed at once to hospital. Immediately it was found that the retailer himself and four members of his staff gave positive reactions and were therefore possible carriers they were forbidden to have anything to do with the milk, and were subsequently removed to special accommodation in the West Herts Hospital. Premises have been disinfected and efforts have been made to isolate the dairy as far as possible from the house.

*Present Position and Future Action*

The present indications are that the outbreak has been checked, although Dr Thomson and his colleagues cannot be quite confident of this for a week or ten days. One or two sporadic cases not within the main group infection are likely to occur and some cases of delayed diagnosis within the group itself are being reported. The fever is a well marked paratyphoid B infection. Some cases are severe, but many are comparatively slight. All the patients are reported to be doing well and no deaths have so far occurred.

In regard to future action Dr Thomson has made a number of recommendations, more particularly as to the requisition by the milk retailer of new premises for his business away from the house and the installation by him of a pasteurization plant. As regards farm X Dr Thomson reports that some alterations are necessary if even a relatively clean milk is to be obtained. The yard requires to be cleaned drained, and lined with flints; a new and larger milk house is necessary and some arrangements for sterilizing the milk churns are required.

## Scotland.

### ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW *President's Budget.*

On the conclusion of his term of office the retiring President Mr R M Buchanan presented to the Royal Faculty of Physicians and Surgeons a budget of office to be worn by the President and at the November meeting he introduced with it his successor, Dr G H Edington.

The badge is in the form of an oval medallion in gold on the obverse of which are the armorial bearings of the Faculty.

The bearings are in enamel of the appropriate heraldic colours. They consist of a shield with in first and fourth quarters azure an Aesculapian rod in pale between a lancet on the dexter and a poppy slipped and eeded on the sinister all proper in second quarter the Royal Arms of Scotland and in the third quarter the arms of the city of Glasgow. Above the shield is placed a helmet befitting the degree of the Faculty above which is the crest an open book surmounted by an antique burning lamp and over all the motto *Conjuncti amici*. The

supporters are dexter Minerva and sinister Hygea and on a compartment below the shield this motto *Non vivere sed valere vita*. The reverse of the medallion is inscribed *Donum dedit RMB MCMLXXXVII*.

The ornaments which were adopted in 1863 in substitution for the previous armorial symbol were matriculated in 1910 following on the grant of the title 'Royal' by King Edward VII. At the time of their adoption careful search of the records of the Faculty failed to throw any light on the date or the circumstances of the adoption of the previous symbol. The old symbol was the rod and serpent in the centre or a shield and flanked by lancet and poppy and the motto was the *Conjuncti amici* of Horace, which might be considered an allusion to the dual composition of the Faculty. The badge which is worn suspended round the neck by a dark blue ribbon, was designed and manufactured by Edwards of Buchanan Street Glasgow.

### PRESENTATION TO DR HUGH MILLER

Dr Hugh Miller who was recently appointed one of the district medical officers to the Scottish Board of Health was entertained at dinner by his former professional colleagues in Hamilton on November 5th, and was presented with a tibia in recognition of his service in theburgh. Dr J Livingstone Loudon M.O.H. for Hamilton presided and the company included most of the medical practitioners in the neighbourhood. Dr Miller was educated at Ayr Academy and Glasgow University where he graduated in 1889. He afterwards held numerous medical posts in various hospitals, including that of house-physician to the late Sir William Gardner. For several years he acted as

secretary of the Hamilton Burgh Panel and Medical Committees and took a great interest in the working of the Insurance Act. Dr Miller was an active worker for the British Medical Association; he has been a member of the Central Council since 1921, has served on the Ethical, Central Emergency and Psycho-Analysis Committees, and has just vacated office as chairman of the Scottish Committee. During the war he held a commission as captain in the R.A.M.C. and served in India.

### GLASGOW UNIVERSITY COURT ASSASSORS

The appointment of assessors on the Glasgow University Court from the General Council of the University has caused considerable interest. For the first time an effort was made by the women graduates of Glasgow University to obtain the election of a woman for one of the vacant posts. The two posts were rendered vacant by the retirement of Dr David Murray and Dr George S. Middleton, of whom the latter did not desire re-election. Three candidates were proposed at the meeting of the General Council on October 26th—David Murray LL.D. J. F. Fergus M.D. and Miss Helen Rutherford M.A. The election of Miss Rutherford to one of the two posts would have meant the displacement of either the legal or the medical representative, and a poll was therefore demanded of the University members. Dr David Murray received 4165 votes, Dr J. F. Fergus 3649 and Miss Helen Rutherford 2825. The two former were therefore declared elected.

### MEASLES IN GLASGOW

An epidemic of measles prevails in Glasgow, although it is regarded as being of a mild type. The winter prevalence of both measles and pneumonia is said in a health bulletin issued by the Public Health Department of Glasgow Corporation to have begun about six weeks sooner than has been customary in past years. This it is thought probably means that the incidence of these diseases will reach considerable dimensions during the next few months. In regard to measles 227 cases were registered in September and 1,208 cases in October. The cases are fairly generally spread over the city and in this respect the epidemic differs from that of 1925-26 which extended slowly from one district to another.

## Ireland.

### CANCER RESEARCH

At the annual meeting of the Linen Guild of the Royal City of Dublin Hospital Dr Moorhead in proposing a vote of thanks to the chairman remarked that in ancient Ireland it was the custom for the chieftains in every district to assemble all the women of the district from time to time in the great halls of their houses in order that they might be taught the arts of housecraft and more especially the arts of needlework and of embroidery. The work thus done served the needs of neighbouring houses and this custom might be regarded as constituting the real origin of linen guilds. In modern hospitals linen guilds played an important part and this made an enormous difference to the comfort and welfare of the patients. Dr Moorhead then referred to the question of amalgamation of hospitals. Three years ago five of the Dublin clinical hospitals had agreed to amalgamate on condition that sufficient money could be obtained for the purpose. He regretted to say that it had been impossible to obtain the necessary financial aid either from public subscriptions or from the Rockefeller Institute and he wished to state definitely now that the question of amalgamation at any rate on a big scale must be abandoned. He was anxious that this fact should be known because many people were unaware that the scheme had been abandoned. He felt that for the present each hospital should endeavour to rally around it its own supporters and to develop on its own lines. He congratulated the board of the Royal City of Dublin Hospital on its courage and foresight in establishing new wards and a new therapeutic department for cases of malignant disease. He thought it probable that a result of close investigation and study of cancer in the new wards

combined with investigation of different methods of treatment, many new facts of importance would be brought to light. Mr. Seton Pingle, in seconding, said that the Governor-General had consented to open the new cancer and deep therapy department of the hospital, and he wished to take this opportunity of dealing with a possible misapprehension on the part of the public. He did not want them to confuse this new hospital department with another new effort in connexion with the cancer problem, of which he hoped a good deal more would be heard as time went on. He referred to the National Cancer Campaign (Ireland), it was concerned entirely with research into the cause of, and the results of treatment in, cancer. It was controlled by a council consisting of delegates from most of the scientific bodies in Ireland. This council had no connexion financially with the hospital authorities, nor was it in any way under their control. The hospitals had merely offered to the council the use of three laboratories, where the scientific work would be carried on. This offer had been accepted as the council recognized the necessity of starting research in a small way, but the National Cancer Campaign looked forward to a time when its financial position would be such as would permit of its having a Cancer Institute on the same lines as in other cities. In the meantime although the laboratories happened to be situated in a wing of the building, their work was absolutely independent of the hospital. The motion was adopted. The Governor-General of the Free State then declined open the new deep therapy and scientific research wards.

## England and Wales.

**QUEEN'S HOSPITAL, BIRMINGHAM.** NEW SURGICAL BLOCK. SIR CHARLES HIND, president of the Queen's Hospital, Birmingham, opened on November 16th a new surgical block which has been erected at a cost of nearly £100,000. The new building is placed behind the old surgical block, and is U-shaped, with wings running north and south, and a central court 50 ft wide. Three large operating theatres are provided on the top floor, connected by two sterilizing rooms. The theatres are airy and well lighted, the equipment is modern, and the walls are covered by opaque glass, coloured grey in two cases and mottled green in the third. The six new wards contain 120 beds, and in the basement is a nurses' dining room. It is hoped that the hospital will now be able to receive 1,750 more in-patients each year, that earlier admission of urgent cases will be facilitated, and that there will be an expansion of important special and auxiliary departments in the old surgical block, which is freed for them. The Queen's Hospital, which was founded in 1840, was enlarged in the years 1850, 1871, 1887, and 1908, a new medical block being provided in the last-mentioned year.

### THE ORTHOPAEDIC HOSPITAL IN LONDON

Prince Henry, KG, presided on November 22nd over a meeting of friends and subscribers to the Royal National Orthopaedic Hospital, London, in its new out-patient department, of which we gave an account last week (p. 946). In asking the Lord Mayor formally to open the new buildings and altered old premises, he probably surprised his hearers by telling them that the additions and alterations were paid for, and that he did not appeal for funds for them. But he did appeal for a sum of £40,000 to complete the payment for the new wards and accommodation for children in-patients at the country branch at Stanmore. He pointed out that an orthopaedic hospital is not made in a day, nor is an orthopaedic surgeon. We would add that the competent orthopaedic surgeon takes far longer to make than the hospital, a fact which is sometimes forgotten in these days of rapid expansion. Prince Henry reminded his hearers that this hospital was the first with which he became officially associated. He has shown in the most practical way the depth and permanence of his interest in it. Sir Charles Batho, the Lord Mayor, in declaring the new buildings open, cordially commended Prince Henry's efforts on behalf of the crippled children, and added a plea for the adult cripple, for whom increased provision is needed. He hoped that something

might be done to hasten their admission, including among them cases of fracture, which were falling more and more into the hands of orthopaedic surgeons. After the meeting the numerous company enjoyed opportunities of inspecting the wall paintings in the waiting hall, as well as the excellent arrangements made for massage and physiotherapy and light treatment of various kinds.

### AMERICAN HOSPITAL POLICY

SIR,—In connexion with your abstracts of, and comments on, the report recently presented to the Legislative Assembly in Victoria by the Hon. Dr. S. S. Argyle on the results of a tour made in the early months of this year by a Melbourne delegation in Canada and the States, it may be permitted, in view of the problems involved, to furnish some additional details.

This visit to Canada and the States was the direct outcome of an invitation to the Dean of the Faculty of Medicine of the University of Melbourne by the Rockefeller Foundation. In view of the wide interest of the problems with which the Melbourne Faculty of Medicine was confronted in the possible rebuilding of its medical school and University hospital, the Trustees of the Rockefeller Foundation kindly offered me the opportunity of a tour of inspection amongst the leading Canadian and American medical schools and hospitals, and the Dean and Faculty accepted the invitation with gratitude. In view of the importance of the principles involved the letter of invitation was submitted to the then Government of Victoria. The Government wisely decided to send two delegates of their own—namely, the Hon. the Chief Secretary of State, Dr. Argyle, and the secretary of the Charities Board of Victoria, Mr. R. J. Love.

The immediate problem before the Faculty of Medicine in Melbourne is not the "improvement of hospital accommodation" in that city, for the Melbourne hospitals are in the first rank, and will stand comparison with those of other countries. Nor are we vitally concerned with "better methods of training medical students," for the Melbourne graduate is to be found in many lands and in many responsible positions. Any properly constituted and appointed medical school has to-day the more important role of adequately advancing the national health rather than the mere technical training of students of medicine. The Melbourne problem is, then, that which now everywhere confronts medicine—the seeking of the best combination of research, teaching, hospital, and laboratory in the cause of the national health—that is, the elimination of disease by study, research, and co-operative effort.

Since 1918 a very great change has been wrought in almost every one of the best Canadian and American medical schools. They have been largely reconstituted, rebuilt, reorganized, and often boldly removed from inadequate to adequate sites, and always with the same object—the concentration on the one spot of laboratory, hospital, and clinic with the purpose of establishing great medical centres for the study of disease and the betterment of humanity.

Striking, drastic, and dramatic changes are now everywhere seen in medical and hospital circles in Canada and the United States, and American concepts of medical education and research are widely apart from British. To attribute to older methods all the virtues and to deny them to the new, or vice versa, would be mere futility.

Political necessities demanded the prompt return of Dr. Argyle to Victoria, but Mr. Love and myself have both been enabled to continue our observations in Great Britain, and our respective reports have yet to be submitted. But the problem before us in Melbourne, in Great Britain, and in the world of medicine everywhere is, given the opportunity of commencing afresh, what is the best we can do for the patient, the nation, and the future of the national health by a wisely co-ordinated system of hospital, laboratory, and united medical effort—I am, etc.,

RICHARD J. A. BERRY,  
Dean of the Faculty of Medicine, University  
of Melbourne

Bristol, Nov. 14th

### IRCOSTEROL VITAMIN D, AND RICKETS

SIR—The very valuable article on this subject in your issue of November 12th contains a slight historical inaccuracy to which I think it worth while drawing the attention of your readers, since it puts in a wrong perspective the work done by the pioneers of this subject, work which, though not yet complete has already produced such an amazing harvest in the improvement of the national health.

You say that "Mellanby, in 1919, suggested that rickets was a disease due to the absence from the diet of some accessory food factor, probably vitamin A" (Italics are mine). In fact, Professor Mellanby published the results of his experiments on dogs in January, 1918. These experiments did not suggest but demonstrated, that in experimental animals in the laboratory rickets, or at all events a form of osteopathy of the bones indistinguishable from rickets could be produced and controlled by dietetic factors alone, apart from other environmental change.

A reference to the literature will also show that it is an error to say that in 1919 the Glasgow school contended that rickets could be prevented by fresh air and sunlight. The Glasgow doctrine at that date was that rickets could be prevented by fresh air and exercise. Massage was advocated as part of the treatment. This doctrine was fully developed in *The Study of Social and Economic Factors in the Causation of Rickets*, which was compiled by Miss M. Ferguson, working under the direction of Dr Noel Paton and Leonard Lindley and published in 1918 by the Medical Research Committee with an introduction by Professor Lindley. In the whole of this valuable document I have been unable to find a single reference to light as a factor in the prevention of rickets but among the "conclusions" are the following:

16 The evidence is against a deficiency of milk of butter or of the fat-soluble substance being a determining factor.  
17 Inadequate air and exercise seem to be potent factors in determining the onset of rickets.

More recent research on the effects of ultra violet irradiation both of living tissues and of the inorganic elements of diet gives to the conclusions a quaint historical interest. Of course Mellanby has not only admitted but emphasized the importance of general hygienic conditions as a contributing factor in the production and prevention of rickets, and to provide the suitable environment must always remain the principal aim and duty of the public health service. But inasmuch as that service not dealing with individuals who must live for at least another generation in an unsatisfactory environment and since in this country we cannot command sunshine I am convinced that it is for us administrators to tie the production of rickets on the lines marked out for us by Mellanby. I do not minimize the value of artificial ultra violet lamps but I am convinced that instruction in diet and the provision of cod liver oil gives a better return for the expenditure of public funds—I am etc.

### THE PHYSIOLOGY OF DEFAECATION

SIR—In your review of Sir Ashburnham Lines' *Secrets of Good Health* in the *BRITISH MEDICAL JOURNAL* of October 29th it is stated that the author appears to be altogether dissatisfied with one good evacuation of the bowels a day and suggests that in the natural state defaecation would follow each meal and that this habit should be cultivated. Your reviewer goes on to quote a passage in which it is said that suitable foods will facilitate such a habit—and then to dismiss the advice with generic ridicule. There may be persons—your reviewer admits to whom such a sequence of events would prove an advantage—but many he thinks will say: Let me eat unsuitable foods and leave me to my one good action a day.

I thought that it was now a commonplace of physiology that the caecum evacuates its contents into the ascending colon within some twenty minutes of a meal and that when the stomach "takes in" (a casualty clearing station) it sends a message—not along its line of communications, if we use so term the small intestine—but by some hormone nuclei or some reflex, or both—"evacuate" to its "bag," the caecum.

I thought that it was agreed that the sigmoid and descending colon move in effort simultaneous with the heave of the caecum and ascending colon and that then, and in normal conditions not till then, should the rectum be filled. And is it not agreed that when the rectum is filled and thereby stretched sensation arises, the first direct sensation connected with the alimentary process since the food was swallowed and that normally the reflex act of defaecation is released from inhibition at the first convenient moment?

If these things be so, then it is not normal for the rectum to stand filled. It is a canal only and not a dock. Mr Paterson held that the part of the rectum below the third valve of Houston is normally empty except during defaecation, and Houston himself held that his valves served to support the weight of the faeces and to prevent their premature urge into the rectal ampulla below. No doubt there is an appreciable period for accumulation above the valves preceding the final evacuation but that period is normally brief—so I think it will be agreed—and it is no more normal for the rectum to stand filled than it is for the mouth and oesophagus to stand filled. The parts of the digestive tract from which direct sensation is derived should normally be emptied as soon as, or almost as soon as, filled.

Dr Hirst of Guy's observed the sudden caecal heave on the x-ray screen about 1912. I fancy he was the first to note it, but his observation has been repeatedly confirmed. This has given a precision to our knowledge which should be reflected in the guidance we give to our patients. Many practitioners must have found that the mere insistence on two or possibly three actions a day—action to be invited by habit to follow the principal meal—has resulted in the cure and comfort of numerous patients who suffered before with reflex dyspepsia to which they had been inclined not without reason to ascribe grave and alarming habits. And diet and habit play a greater part in this cure than laxatives.

I belong Sir to the ranks who derive special benefit from your admirable reviews or books and I trust you will attribute to jealousy for the high standard of judgement the *Journal* maintains this venture to question that judgement in a particular instance—I am etc.

Home's Chapel, Chesham, Nov. 12th  
LIONEL JAS. PRYOR

### SOME EFFECTS OF LIGHT

SIR—I have read the communication published by J V Supniewski in the *Journal of Physiology* (vol. lxxv No 1, Oct. 1 1927) which was reviewed in your issue of November 18th (p. 947). The author appears to have failed to recognize the recent investigations in this country on the action of light on ensitized organs. Argyll Campbell and Leonard Hill have described the effects of light upon leucocyte and blood vessels in the mesentery of living animal (*Journal of Path.* 1924 vol. v p. 317). Auer and Leonard Hill have published results of experiments on the effect of light on the frog's stomach and large intestine the rabbit's large intestine and the guinea pig's non-pregnant uterus (*Proceeding Royal Society Series B* 99 1925 p. 221 226). The latter experiments are practically identical with those described by J V Supniewski and show similar results—I am etc.

### COLOUR VISION

SIR—The critic of the report of the British Association on colour vision (November 12th p. 289) does not recognize its importance. It is the second great advance on the subject the first being when the wool test (which allows 50 per cent of dangerously colour blind to escape detection, and

<sup>1</sup>Proc. Physiol. Soc. Journ. Physiol. 57, 1918  
*British Medical Journal*, November 7, 1922.

<sup>2</sup>*Journal of Anat. and Physiol.* 31, 1911.

of those rejected by it 50 per cent are practically normal sighted) was recognized as defective. This report establishes the fact, which is known to all who have even a small practical acquaintance with the subject, that there are defects of light perception independent of defects of colour perception or colour discrimination, though they may be associated. A man may have shortening of the red end of the spectrum and have normal colour discrimination, just as a man may not be able to hear certain low notes and yet be a musician. The old terms are useless, and the facts do not comply with the definitions, there are not two or three definite varieties of colour blindness, but innumerable degrees of both defects. Of the very large number of cases of colour blindness I have examined, running into thousands, scarcely two are exactly alike. The classification dichromic and trichromic the two dangerous varieties of colour discrimination, is only fact, and has nothing to do with theory. The dichromic see two colours in the spectrum and a neutral division. The trichromic see three colours in the spectrum—red, green, and violet—but there are innumerable varieties of both. For instance, the dichromic have a neutral band of varying size or a varying degree of shortening of the spectrum, and the yellow region which the trichromic call red-green varies in size in different cases.

Two very able men have been added to the committee—Professors Andrieu and Hartnidge—and there is every reason to hope that next year the report will correct some more misstatements, such, for instance, as that the tortoise has only cones, and that the Purkinje phenomenon and recurrent image are not found with the fovea—I am, etc.,  
London, N W 2 Nov 19th F W LDRINGL-GRIFFIN

#### TREATMENT OF PROSTATIC ENLARGEMENT

SIR,—I think most of those engaged in general practice regard prostatectomy as a grave and often disappointing operation. The old method of leaving a ragged and infected cavity led constantly to delayed union of the suprapubic wound, with the accompanying irritation and mental depression produced by a constant leakage.

The most complete relief and rapid convalescence that I have seen followed Young's perineal operation—I am, etc.,  
Milford, Surrey Nov 20th G A CHAMBERLAIN, F.R.C.S.

SIR,—In your report of the Bradshaw Lecture, delivered on November 10th by Sir Cuthbert Wallace, the operative treatment of carcinoma of the prostate is unfavourably criticized owing to the difficulty in diagnosing the condition in its early stage. The later stages of the disease, however, demand treatment, and here surgery has not altogether failed.

The lecturer is recorded as having said that the operative treatment involves the entire removal of the gland. It involves something more than this—namely, the excision of all the tissues which form the base of the bladder and which lie between it and the anterior wall of the rectum.

The operation which I have elaborated and practised is by the suprapubic route, and its technique is described in the *Proceedings of the Royal Society of Medicine*, 1924, vol. xvii (Section of Urology), pp. 43-52—I am, etc.,  
London, W 1, Nov 21st A CLIFFORD MORSON

#### "SYMPTOM-COMPLEX" OR "SYNDROME"?

SIR,—The letter of Dr A. A. Warden (November 5th, p. 848) raises a very interesting question of definition of medical terms "Symptom-complex" and "syndrome" are used in contemporary French clinical teaching, and I think they must be obtained in medical literature because each term has a separate significance.

"Symptom-complex" indicates the series of symptoms (and signs) grouped together clinically without any consideration as to their relationship with a lesion or a functional disturbance of an organ. The particular name given to every "symptom-complex" is purely clinical. By "syndrome" is meant the grouping of symptoms and signs corresponding to a certain deviation of the function of an organ or to a lesion of an organ. There are anatomical and clinico-functional syndromes, and the name

given to each one in particular corresponds to its pathological basis. "Disease" must be considered as constituted by one or more syndromes caused by the same external etiological agent. We speak of disease in terms of that external etiology.

To take an example, pain, rigidity, skin hyperaesthesia of the right iliac fossa, constitute the right iliac fossa symptom-complex which may be met in appendicitis, salpingitis, etc. Pain in the right iliac fossa, rigidity, hyperaesthesia, and other symptoms and signs grouped so as to indicate their relation to the lesion of the appendix, constitute the anatomical-clinical syndrome of appendicitis. We speak of epigastric symptom-complex, of pyloric syndrome, of "disease" syphilis of the stomach.

This terminology corresponds to the evolution of our clinical thinking. Our first step in diagnosis consists in the detection of the various symptoms and signs—that is, of the symptom-complexes. Next, these symptoms are grouped into syndromes, and lastly, the etiology, external or constitutional, of these syndromes is considered. As I wrote in a previous publication, "from the symptom through the syndrome to the disease is the way of clinical diagnostic progression."

It is interesting to note that this ontogeny of our contemporary clinical thinking corresponds to the phylogeny of medicine. Diseases in the times of Hippocrates and of Sydenham were symptom-complexes. Later on, with the advent of the great anatomical-clinical school of Paris, of the famous English clinicians of the beginning of last century, and of physiologists such as Claude Bernard and Johann Müller, it was the syndromes which formed the basis of nosographical classification. Nowadays, after the impulsion given by Pasteur, Lister, and Koch, it is the external etiology which forms the basis of our conception of disease, conception which is in course of modification thanks to the researches on constitutional etiology.

It is interesting also to note that the distinction of these three concepts, symptom-complex, syndrome, and disease, was felt by the ancient Greek physicians, although they had scarcely any pathological or etiological notions. They called *συνδρομή*, the purely clinical grouping of symptoms, *πάθος*, or affection, the grouping of symptoms corresponding vaguely to the alteration of an organ, and *νόσος*, something more limited nosographically. These original Greek terms were used in the teaching of Laennec, but the general tendency is, I think, to call "syndrome" what the Greeks called *πάθος*, and to use the term "symptom-complex" for what the Greeks called *συνδρομή*—I am, etc.,

London W 1 Nov 4th

A. P. CHAMBERS

SIR,—From the point of view of the purist in terminology, Dr Warden's condemnation (November 5th, p. 848) of the expression "symptom-complex" is amply justified and I am with him most cordially. "Symptom" is as certainly of Greek origin as "complex" of Latin. "Syndrome" from the same point of view is decidedly to be preferred.

The chief object of a verbal expression is, however, to convey the intended idea, and nothing else, as accurately as possible. "Symptom-complex" does this quite perfectly, whereas the expression "syndrome" is not confined to symptoms, but has other general applications. "Symptom" is a well established English word and "complex" is now quite naturalized. To join them with a hyphen transgresses no rule of word construction. I am, therefore, in favour of "symptom-complex" all the time—I am, etc.,  
November 11th J. D.-G.

#### MEDICAL CONFIDENCES

SIR,—May I comment on certain statements in your "Medical Notes in Parliament" (p. 963), as they concern a bill I introduced this afternoon in the House of Commons?

The statement to which I take objection is as follows: "The Parliamentary Medical Committee has not been consulted in the preparation of the bill. A deputation of medical members of Parliament to the Minister of Health on the same subject had previously been suggested, though no arrangements had been made for it."

I submit that the implication is that I took action in a

matter which had been under the consideration of my colleagues without informing them of my intention and that I, as secretary of the Committee, had failed to make arrangements which the Committee had desired should be made. In reply I have to say that this subject has never come before the Parliamentary Medical Committee, that I am in common with a large majority of my colleagues, had no knowledge of the suggested deputisation and I do not know when or how the suggestion was made.

Upon the eve of the autumn recess in July last in conversation upon the McCauley judgement with a couple of barrister friends of mine in the House, one of them suggested to me that I should introduce a bill under the ten minutes rule which would make such a judgement impossible for the future and both promised me their support and assured me that the lawyers would make no objection. I prepared the bill during the recess in consultation with a barrister friend who is skilled in Parliamentary draftsmanship, and I presented my motion for its introduction upon the day after Parliament reassembled.

There was no opportunity of consulting the Parliamentary Medical Committee had I wished to do so for we have not yet met this session. Opposition to my bill was not to be interpreted from the medical members, in view of the overwhelming desire of the medical profession as evidenced by the medical press for a change in the law relating to medical evidence. I consequently concentrated my attention on winning the assent of legal members of the House to the principle of my bill, for opposition, if any was to be interpreted from the lawyers more particularly and the final drift of my bill is the result of consultation with several leading counsel in the House.

Two members of the Parliamentary Medical Committee are bringing my bill many more would have done so had the number permitted by the rules of the House not been so restricted. Your note I submit suggests some sense of grievance against my action which I am assured does not reflect the predominant feeling of the Committee—I am, etc.

House of Commons Nov 22nd

E CHAMBERS LITTLE

## THE ROYAL COLLEGE OF SURGEONS OF ENGLAND AND ITS MEMBERS

SIR—The impression left on my mind after the thirtieth annual meeting of the Fellows and Members of the Royal College of Surgeons of England on November 17th was one of progress having been made since last year's meeting. Previous presidents to cover a weak defence, resorted to the gullarmie method. There was none of that this time. The President gave a patient hearing, and appeared to me to be impressed by the fact that there was greater strength on our side than he had anticipated. One thing now seems impossible for the President to withhold—namely a postcard plebiscite of the Members as to their respect regarding this important question. The two excellent speeches by Mr Lawson Dick, FRCS, and Dr Stella Churchill laid the matter before the Council with a clarity hardly ever before reached moderately and reasonably expressed. The new President of the Royal College of Surgeons has now a unique chance of directing the Council to a wider aspect of the matter than has hitherto been done.

As a Member of the College I have pride in our splendid institution. The museum is one of the finest in the world and the library is invaluable. We cannot but be in admiration at the way all is managed and also at the never failing courtesy of the clerical Sir Arthur Ierth. One thing and one thing alone is lacking. It is the wish of the Members that they may be permitted in the humblest manner, to participate in the advancement of a centre of such useful and noble activity that this great institution by combined research and professional unity, may become even greater still—I am, etc.

Letter Nov 19th

T WILSON PARRY

\*\* A report of the annual meeting of Fellows and Members of the College is printed on this page.

## Universities and Colleges

### ROYAL COLLEGE OF SURGEONS OF ENGLAND

#### ANNUAL MEETING OF FELLOWS AND MEMBERS

THE annual meeting of the Royal College of Surgeons of England took place on November 17th with the President (SIR BENJAMIN MOYANIAN, Bt.) in the chair. There was an unusually large attendance of Members and for the first time ladies were seated in the body of the theatre instead of in the galleries.

THE PRESIDENT in making some remark on the annual report of Council referred to the gift by Mr Buckton Browne (Fellow) of a sum of £5,000 the interest on which is to be expended on providing an annual dinner on the College premises for Fellows and Members and such others as the President and Council may wish to invite but at least half the guests are to be Members. He also announced with regret that Mr F G Hallett was retiring from the secretarialship of the Conjoint Examining Board after fifty years of the most skilful and devoted service in one or other capacity. The number of diplomas of Membership issued during the past year had been 700 (including 117 women) of Fellowship 60 (one woman) and of Licentiatehip in Dental Surgery 169 (12 women). The number of Membership diploma continued to be very high the average before the war was between 200 and 400 a year. He next referred to the action taken by the Council on the resolution of the last annual meeting calling for a postal vote of Fellows and Members on the general principle of admitting Members to direct representation on the Council of the College. A subcommittee was appointed by the Council an historical abstract drafted by its secretary was drawn up and Fellows were asked to record their opinion whether it was desirable that Members should have such representation. 1,000 replies were received out of 1,800 Fellows who were circulated 846 voting No and 234 Yes. In view of the result the Council unanimously adopted a resolution that it was not prepared to take step at the present time for altering the constitution of the College so as to give Members direct representation.

Many questions were put to the chair including a series of interrogatories by Dr DELLEGEY designed to elicit how many members of the Council in recent years had been engaged in general practice exclusively or in combination with consultant work. The President said that there had been several members of the Council more especially resident in the province who had combined general practice with other work but very few members of the Council had been men exclusively engaged in general practice. He was able only to mention one name—Mr Sibley—though other general practitioners had been elected to the Council but had not secured election. The President was further asked how the figure of 400 given in the historical abstract as the number of practitioners entirely engaged in consulting surgical work in Great Britain and Ireland was arrived at. The President replied that at the time of the formation of the Association of Surgeons it was considered that nobody should be entitled to join that association unless he was exclusively engaged in surgical practice and a circular was sent to members of surgical staffs all over the country asking for such names. The number arrived at by this means was rather below 400. The Member who had raised the question said that an examination of the director suggested that in London alone there were at least 300 such men and he thought the number 400 was too small an estimate for the country at large.

DR ERNEST E. WARR then moved the usual resolution affirming the desirability of admitting Members to direct representation on the Council to which was added on this occasion an expression of regret that the Council in taking a postal vote of the Fellows should have issued simultaneously a statement of a biased and partisan nature and should have omitted to elicit the views of the Members at the same time as the Fellow. Dr Warr said that a similar resolution had been moved in that theatre at thirty-eight previous annual meetings a remarkable testimony to the Members long suffering. That a corporate body with 1,800 Fellows and ten times as many Members should refuse all representation to the latter although they were its financial stand by was an anomaly of the worst kind. He hoped that the Council would even yet reconsider the position. He complained of the historical abstract which was circulated to Fellow with the voting paper it was nothing less than an attempt to secure a negative vote. Although the Members had met with heart-breaking rebuff they would persevere. The Society of Members had received the services of this stout fighter Dr Sidney Lawrence who had retired after eighteen years of fine service but Dr Pinto-Lima had taken his place and the work would go forward until eventually the College discarding one precedent would grant direct Member franchise and representation the demand.

MR LAWSON DICK (Fellow) seconded the resolution and said that he had been for many years in full sympathy with the Members in their desire for direct representation. The Council

sent out by the Council contained such biased comment that no Fellow receiving it could help coming to the conclusion that the Council was entirely opposed to this change. The Society of Members in its turn naturally circumscribed the Fellows so that what was asked for at the last meeting, a simple expression of opinion as to the justice of allowing Members some form of direct representation, was converted into a keen controversy. He was convinced that John Hunter, on the ground of medical education alone, would have deeply sympathized with the wish of the Members. Could it be contended that the Fellows as such were so much better informed than the great body of the Members as to the type of education and examination which was most likely to be helpful to future generations of practitioners who were to occupy the places they at present held? To day the position of the consultant was better defined and more assured than ever it had been, but at the same time there had been an enormous levelling up of the standard of the profession as a whole, and any such rigid distinction between Fellows and Members as the present mode of election to the Council implied was an anachronism which should be ended. Should the special experience of the Members, who in a very intimate degree were in the confidence of the family life of the nation, be ignored? "Jes e Fool," said John Hunter, "accuses me of not understanding the dead languages, but I could teach him that in the dead body which he never knew in any language, dead or living." With equal truth and less respect the Members might well say, "We can teach you concerning the living body, politics of the nation things you can never know till you have listened to the united voice of your Members, who have the care of the national weal so largely in their hands and the pride of their College so largely in their hearts."

Dr STELLA CHURCHILL, the first woman Member of the College to speak in these annual discussions, thought that there was hope in the fact that the Council was not so reactionary as it thought itself, at least it had opened the doors of the College to women, now for some years past. She thought it quite possible that people who lived in the sanctified atmosphere of the Fellowship could not be in touch with the Members. One of the principles of the constitution was "No taxation without representation. What harm could possibly accrue to the Council from having Members representation?"

Dr REDMOND ROCHE asked what fair minded man would have thought it possible that the Council, in replying to the resolution of the last annual meeting would decide to poll, not the 18,000 Members as to whether they desired this representation, but the 1,800 Fellows whose vested interests, it was suggested were going to be infringed? He showed that history had repeated itself in this matter that in 1897, when the Council took a vote of its Fellows, a biased circular was issued with the polling cards. The Council, however, had power, as it had acknowledged on one occasion, to initiate action and reform apart from and in spite of the votes of the Fellows. He therefore urged that it should not be taken that the recent vote of the Fellows decided the question. In introducing electoral reform a Government did not take a referendum of the existing electorate, nor even of its party followers. It took its courage in its own hands, and did what it considered right. He hoped the Council would do the same.

Dr F. W. COLLINGWOOD, Dr HOWARD STRATFORD, Dr KINGSFORD, and others all spoke in support of the resolution, which was carried by a very large majority, two Members, one of them a woman, dissenting.

The PRESIDENT said that he would see that the resolution was submitted to the Council at its next meeting. He was sure that he would be supported by other members of the Council present in testifying that the friendly spirit shown in that debate was reciprocated in the Council itself, where the Members had some very good friends and convinced supporters of their cause. He wished that there had not been criticism of the historical abstract, for he believed that there was not a phrase in the abstract which could be controverted. It was as accurate as any human document could possibly be. (Dr SIDNEY LAWRENCE and others "We don't agree.")

#### UNIVERSITY OF CAMBRIDGE

Mr GEORGE EDWARD WHERRY M.A., M.Chir., F.R.C.S. university lecturer in surgery, consulting surgeon to Addenbrookes Hospital and for many years an examiner in surgery for the third M.B., has been elected an Honorary Fellow of Downing College.

#### UNIVERSITY OF LONDON

Dr J. A. BRANTON HICKS has been appointed as from September 1st to the University readership in pathology, tenable at the Westminster Hospital Medical School.

Sir WILMOT P. HARRINGTON KCMG CB MD, FRCP, has been appointed the representative of the University on the Organizing Committee of the International Congress of Military Medicine and Pharmacy to be held in May 1929.

Miss M. S. JEVONS M.B., B.S., has been appointed a governor of Rye Grammar School.

Sir Holburt Watney has been elected chairman of the Don and Annual Sanatorium Institution Committee for 1927-28.

Messrs J. Lyons and Co., Ltd., have made a gift of 250 guineas towards the establishment of the proposed chair of dietetics.

#### UNIVERSITY OF SHEFFIELD

The Council, at its meeting on November 11th made the following appointments: Percival J. Day, M.D. Ed. to the post of honorary lecturer in ophthalmology, J. L. Groot, F.R.C.S. Ed., D.M.R. Camb., to the post of honorary lecturer in radiology.

#### VICTORIA UNIVERSITY OF MANCHESTER

At the meeting of the Court of the Victoria University of Manchester, on November 16th, it was decided on the recommendation of the Senate and Council to confer the title of Professor *lauratus* upon Professor R. B. Wild on his retirement from the Leech chair of materia medica and therapeutics.

#### UNIVERSITY OF LEEDS

The Council of the University has appointed Dr Edwin Holmes to be surgical tutor in the School of Medicine, and Dr G. Baxter as an honorary clinical tutor in the School of Dentistry.

#### ST. ANDREWS UNIVERSITY

Dr ROBERT RICHARDS, lecturer in forensic medicine in the University of Aberdeen, has been appointed to the additional examinership in forensic medicine rendered vacant through the resignation of Professor Matthew Hay.

### Medico-Legal.

#### VENN v. TODESCO AND ELDER

##### A THIRD HEARING VERDICT FOR DEFENDANTS

THE third hearing of the action of Mrs. Mary C. Venn of Thornton Heath, suing as a poor person, against Dr. James M. Todesco, resident superintendent of the Croydon Borough Isolation Hospital, and Dr. G. W. Elder, formerly assistant medical officer at the hospital, for damages for alleged negligence resulting in the death of her husband, Mr. W. E. Venn, notary public, ended with a verdict for the defendant doctors by a special jury in the King's Bench Division of the High Court of Justice, before Hordidge, J., on November 17th.

A case has now been disposed of which has occupied nineteen days of judicial time. The first hearing, before Lord Hewart, L.C.J., in June, 1925, occupied five days, and the second hearing, before McCrindle, J., in February, 1926, occupied eight days, on each of these occasions the special jury disagreed upon the issue of negligence, which defendants denied. The last hearing occupied six days.

Reports of previous hearings appeared in the *British Medical Journal* of July 11th 1925 (pp. 92 and 93), of March 6th, 1926 (pp. 459 and 460), and of May 1st 1926 (p. 812).

Sir H. Maddocks, K.C., and Mr. B. Mark Goodman appeared for the plaintiff, Mr. A. Neilson, K.C., and Mr. T. Carthew for the defendants.

Mr. Maddocks, in his opening, said that in February 1922 Mr. Venn contracted scarlet fever and after about a fortnight he suffered great pain in his right thigh, and a swelling appeared. His doctor, Dr. E. G. D. Milson, diagnosed a deep seated inflammation which might lead to an abscess and necessitate an operation and therefore arranged for Mr. Venn to go into Croydon Borough Hospital. Soon after his reception Mrs. Venn told Dr. Todesco and Dr. Elder what Dr. Milson had diagnosed but they both "pooh poohed" the possibility of an abscess. Dr. Elder said that Mr. Venn was suffering from rheumatism, and Dr. Todesco expressing the opinion that it was a case of mind over matter and that if Mr. Venn would forget his leg it would soon be all right. In April Dr. Veitch Clark, the medical officer of health for the borough examined Mr. Venn, and ordered his removal to the Croydon General Hospital where in operation was performed and a large abscess was found which should have been previously diagnosed at the borough hospital. On June 15th Mr. Venn died from blood poisoning.

Evidence in support of counsel's statement was given. Mr. Neilson, opening for the defence said the two defendants were both qualified medical practitioners but it was suggested that by their carelessness and negligence they had failed to that by the presence of the deep seated abscess from which Mr. Venn suffered. Diagnosis of that particular thing was from its very nature and position one of the most difficult problems that a doctor had to solve. No indication had been given on behalf of the plaintiff of when the defendants should have diagnosed the abscess. No one had said that it could have been diagnosed before April, 1922 and that was the first date on which any doctor could reasonably have been expected to diagnose it.

Dr. Todesco in evidence, said that when he saw Mr. Venn on the day after his admission he did not find any abscess or any deep seated inflammation. He denied having told Mrs. Venn that her husband was worrying about his leg, and that it was a case of mind over matter.

Dr. Elder in evidence said the day after Mr. Venn's admission he asked him whether he could account for the swelling on the

thigh and Mr Venn replied that he had been a martyr to rheumatism and had buried him self in using a hot water bottle to relieve the pain. Mr Venn never told him that Dr Milom had sent him to the hospital to have the thigh treated.

Dr P Veitch Clark medical officer of health for Manchester who occupied a similar post at Cradock in 1922 and who was originally a co-defendant but was entirely exonerated by the jury on the first hearing said in evidence that when he saw Mr Venn in the first week of April 1922 there was no swelling on the right thigh but on April 25th he found a swelling and evidence of fluid and in trusted Dr Todeco to call in a surgeon. In his view the abscess could not have been discovered before that date.

Cross-examined Dr Clark was prepared to swear that Mr Venn never told him that she would like a specialist to see her husband.

After an absence of twenty five minutes the jury returned a verdict in favour of the two defendants and judgement was entered accordingly.

## Obituary

### GEORGE COWELL, F.R.C.S.,

Consulting Surgeon to Westminster Hospital and the Royal Westminster Ophthalmic Hospital

WE have to record with regret the death on November 18th of Mr George Cowell at the age of 92. He was a well known figure in the medical world of London during the last thirty years of the last century and at the beginning of this. He was the son of Mr G. K. Cowell, surgeon of Ipswich, and was born on June 1st, 1836. He received the earlier part of his medical education in Birmingham, where he was apprenticed, as was then the custom afterwards he entered the medical school of St George's Hospital, and took the diploma of M.R.C.S. Eng. in 1858. He became F.R.C.S. in 1867. Shortly afterwards he was appointed assistant surgeon to the Westminster Hospital, and soon afterwards surgeon, an office he held from 1869 to 1895. He was lecturer on surgery there from 1872 to 1893. He was surgeon to the Victoria Hospital for Children from 1865 to 1885, and was ophthalmic surgeon to the East London Hospital for Children, Shadwell. He was one of the last to combine the practice of ophthalmology with that of general surgery.

Mr W. G. Spencer, his colleague at the Westminster Hospital, says of him that 'in general surgery he had accepted Lister's methods without attempting to extend the scope of surgery which those methods facilitated. The special attention he had devoted to ophthalmology seemed to dispose him to smaller operations and finer manipulations.' 'I had watched,' Mr Spencer adds, 'as did Mr Henry Power and Mr Bowater Vernon when operating for cataract, and when subsequently I came to help Cowell I formed the opinion that his handiwork was not then to be bettered.' When Mr Spencer was elected assistant surgeon to the Westminster Hospital in 1887 Mr Cowell was the senior surgeon, and for many years remained the senior of the medical staff. He headed its efforts towards making various improvements at the hospital and in the medical school. As a chairman his efforts were always directed to facilitating business. Mr Spencer states that soon after his appointment Mr Cowell called a meeting at his house, at which he and the late Charles Stonham were invited to express their opinions. Mr Cowell took an active part in bringing about the rebuilding of the medical school, the out-patient department and the chapel of Westminster Hospital and until his final retirement in 1897 took an active interest in the hospital and its school. Afterwards he still continued regularly to attend committees as a vice-president of the hospital until age curtailed his activities, and he was able to head the medical staff at the service in Westminster Abbey commemorating the re-opening of the hospital after alterations in July 1924. With this exception he had been here seen in London for a good many years. He became a member of the British Medical Association in 1870, but resigned on his retirement in 1897.

Mr Cowell was a deeply religious man, he took a leading part in the Guild of St Luke and was associated with Dr Barnardo in founding the charitable association which has since developed into the Barnardo Homes. He was a freemason and had attained the degree of Past Grand Deacon of the United Grand Lodge. He did not write much but contributed papers from time to time to the

*Proceedings* of various medical societies, and edited the *Life and Letters of Prof. or E. B. Cowell* who held the chair of Sanskrit at Cambridge. Mr Cowell married rather late in life (1892) the widow of Dr Hamilton Poe, she died in 1895, there were no children of the marriage.

### R. H. A. WHITELOCKE, M.D., F.R.C.S.,

Consulting Surgeon to the Radcliffe Infirmary Oxford

WE regret to record the death on November 18th of Mr R. H. A. Whitelocke. He was the fourth son of the Right Hon. W. A. Whitelocke of Balstrode Park, Westmorland, and was born in January in 1861. He was educated at Owens College, Manchester and the University of Edinburgh where he took the degrees of M.B. and C.M. in 1884. He graduated M.D. in 1903, and became F.R.C.S. Eng. in 1893. He was house surgeon to Sir William Macewen in 1886 and after a period at Moorfields Ophthalmic Hospital went to Oxford in 1888 as demonstrator of human anatomy to Professor A. Thompson. He became surgeon to the Radcliffe Infirmary in 1899 a post he held until 1926. He was Lichfield lecturer on surgery in the University, had been president of the Oxford Medical Society and of the Children's Section of the Royal Society of Medicine. He was a Fellow of the Association of Surgeons of Great Britain and Ireland, and had been vice-president of the Provincial Surgical Club. Immediately after going to Oxford he joined the then recently formed Oxford and Reading Branch of the British Medical Association, and from that date down to his death was one of its most loyal supporters. He seldom missed a meeting and frequently showed cases and opened or took part in its discussion. He was chairman of the Oxford Division in 1909, and president of the Branch in 1910. He took an active part in the Annual Meeting at Oxford in 1904 when he was president of the Section of Surgery, he was afterwards vice-president of the Section of Diseases of Children at the Annual Meeting in Glasgow in 1922.

He was an equally loyal supporter of the Oxford Medical Society and in due course occupied the chair. In addition he was one of six original members of the Oxford Medical Club. It was started in 1891 and consisted of twelve members who met once a month for reading papers or discussing subjects unconnected with medicine, as he was a very regular contributor to those meetings his death will be much regretted by all members. When a few years ago a weekly contribution scheme was started to help the County Hospital Mr Whitelocke gave it his hearty support, and spoke in its favour at many evening meetings in all parts of the district, often in remote villages entailing long motor journeys at night. From the outset of his life in Oxford he strove to qualify himself for a surgical career, and took the F.R.C.S. in 1893. His opportunity came in 1899 when he was made a surgeon of the Radcliffe Infirmary and County Hospital. He very quickly built up a large and successful surgical practice, and found a host of friends and supporters both in the city and neighbouring district. For many years he was regarded as a specialist on football injuries and as consulting surgeon to the University Rugby Union Football Club had unusual opportunities of studying this branch of surgery. During his life at Oxford a very large number of undergraduates passed through his hands, and many of them must have profited by his skill and care. They will be scattered over many lands when they hear of his death they will have with his Oxford friends a very deep regret. He was fond of travelling and especially enjoyed visiting various European capitals in connexion with the meetings of the Provincial Surgical Club of which he was a member. His chief recreation was shooting and he had the reputation of being a very good shot. He was a freemason and a Past Master of the Churchill Lodge.

He was the author of books on sprains and allied injuries of joints and on football, and contributed articles on allied subjects to the *Index of Treatment*, the *Practical and Encyclopaedia of Medicine and Surgery* and the *Proceedings of the Royal Society of Medicine*. Mr Whitelocke left a wife two sons and three daughters. His second son is now one of the honorary surgeons at the Radcliffe Infirmary.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT]

IN the House of Commons this week the Unemployment Insurance Bill was examined in Committee, and discussions arose on foreign policy and on the appointment of a Statutory Commission on the government of India. On November 22nd a joint deputation from the National Council of Social Service and the Mansion House Council on Housing met the Prime Minister and the Minister of Health to advance arguments in favour of setting up a Royal Commission on Housing. Dr. Finliffe was one of the deputation. The Prime Minister could not agree to the suggestion of a Commission. The Landlord and Tenant Bill, the discussion of which on the Report stage was noted last week, was read a third time on November 18th.

This week the Ministry of Health and the promoters of the Nursing Homes Bill were still endeavouring to secure a sufficient approach to unanimity on it to justify the Government affording facilities for its passage into law this session. The point at issue was whether county councils or borough councils should be inspecting authorities, several Labour members insisting on the claim of the latter bodies.

### Medical Confidences

On November 22nd Dr. Graham Little asked leave to introduce the Medical Practitioners' Communications Privilege Bill, which, he said, was a measure intended to remove something like a deadlock which had resulted from a conflict between the Regulations issued by a Government department in 1916 and the law as interpreted by certain recent legal decisions. In 1916 the Royal Commission on Venereal Diseases issued its report. Its personnel was admirably authoritative and representative. It included Mr. Philip Snowden, who had done him the honour to put his name on the back of the bill. Unhappily, there was a popular belief that venereal disease was a special order of disease resulting from excessive indulgence in a normal function, and that this disease deserved punishment and that in some mysterious way the disease differed from other disorders. That view had never been held by the medical profession, and he hoped that it was out of date in this country. There were two dissimilar forms of venereal disease—syphilis and gonorrhoea. The Report of the Royal Commission showed an unexpectedly high percentage of both diseases in this country. It was established by the evidence given before the Commission that syphilis ranked third as a killing disease, coming after cancer and tubercle. Perhaps it ought to come first, because in many cases it produced the two other diseases. Besides being very mortal, particularly among young children, slaying tens of thousands, it was, with its companion diseases, easily the first of all disabling diseases known to day. Syphilis, in particular, was primarily responsible for a large proportion of cases of insanity, and for a long string of diseases of the nervous system which made life a prolonged agony. Evidence was given in the Report of the Commission that at least one in every ten persons in our community was affected, and more than one half the total number of cases of blindness in young children was due to this cause. The medical position of these cases might be summed up in an epigram of a medical man: "Who knows all about venereal diseases knows all about medicine, because they affect every organ and tissue of the body." The state of affairs disclosed by the Report of the Commission was so appalling that it was felt immediate action was called for, and this was happily taken. In consequence and pursuance of the recommendations of the Commission the Local Government Board, in the same year as the Report was published, inaugurated a system of clinics for the treatment of venereal disease throughout the country, and issued regulations for their conduct. The foremost and most important among these regulations was an instruction to medical practitioners and other persons concerned that all information obtained in respect of any persons treated in these clinics should be regarded as absolutely confidential. The evidence before the Commission demonstrated that it was necessary for the success of any measure for the treatment of venereal disease that the patient should be fully assured of secrecy. The reason was surely obvious. Modern methods of treatment have completely revolutionized the prognosis of this disease, but a condition was that early treatment should be instituted. Irreparable mischief might result, and had resulted, from the disinclination of the victims of the disease to consult their family doctor. The reasons for that were obvious. It was almost impossible to have the disease treated at home and to conceal its nature, but the same patient would go to a clinic where he was identified only by a number and where he knew that he would get the very best treatment that the medical science of the time could afford.

Under the present rules patients went to the clinics and received explicit assurance that no information whatever concerning their disease should be divulged, and that assurance was fortified by the issue of a leaflet, in which the same promise was given, emanating from the Ministry of Health, and curbing with it, therefore, the authority of Parliament. The success of these clinics rested upon two factors—the enthusiastic co-operation of the medical practitioners in charge and the complete confidence of the patient treated. That co-operation and that confidence had been abundantly won by the assurance of secrecy. Doctor and patient alike had felt secured by the Ministerial regulations from any possibility of being compelled to make any disclosure of these confidential communications. But the security had been completely shattered by the decision given in Birmingham last July, by Mr. Justice McCardie, when a doctor was ordered to disclose the character of the disease from which his patient was suffering, although he had relied under the explicit protection of the regulations framed by the Ministry of Health. Medical men thus found themselves forced to betray the trust of their patients. That betrayal is really an affront to Parliament, because Parliament must be responsible in some measure for the acts of one of its most important Ministries.

The position which the bill sought to remedy was that complete privilege should be given to communications which had been erroneously supposed for the last twelve years to be privileged. It was clear that either the law must be amended in the way he suggested or that the Ministry of Health regulations must be scrapped. He was encouraged by the opinion of eminent members of the House that any legal difficulty could readily be overcome. If, however, the regulations were scrapped, the fate of a highly successful and important Ministerial and medical effort would be sealed.

The sponsors of the bill were Dr. Vernon Davies, Sir Walter Greaves Lord, Mr. E. C. Grenfell, Mr. Arthur Henderson, Mr. F. B. Meirimon, K.C., Mr. Hopkin Morris, Sir Basil Polo, Mr. Goodman Roberts, Dr. Salter, Mr. Snowden, and Mr. Storry Deans.

Leave was given to bring in the bill, which was formally read for the first time.

**The Anatomy Acts.**—In answer to a question Mr. Chamberlain said some boards of guardians have declined to exercise their powers under the Anatomy Acts to hand over the bodies of paupers who die in their institutions and who are without friends or relatives, to the medical schools for anatomical purposes, but he was not aware that any protest from a board of guardians had been received against a letter issued by his department asking boards of guardians to take this course. Any inmate of an institution could express a desire that his body should be interred without anatomical examination, and the Anatomy Act, 1832, provided that such a wish should be respected. After the examination the bodies were interred in consecrated ground.

**Calf Vaccine.**—Answering Mr. Gioes, on November 17th, Mr. Chamberlain said that the records showed that the lymph now used at the Government lymph establishment was derived from used calf lymph originally obtained from Cologno. The lymph had been carried on by repeated transference from animal to animal. The substances now added to the lymph were glycerin, distilled water and oil of cloves. The lymph complied with the standards laid down in the Regulations made under the Therapeutic Substances Act 1925, but was not completely sterilized, as otherwise its active principle would be destroyed.

**National Health Insurance.**—Sir K. Wood, replying to Mr. Horé Belsha, on November 21st, said that the Minister of Health had received the views of the Consultative Council regarding the proposals made by the Royal Commission on National Health Insurance that the scope of the benefit should be extended to include a consultant and specialist medical service and that the necessary funds for this purpose should be obtained by a partial pooling of future surpluses of approved societies. The council's views were receiving the Minister's most careful attention, but he was not yet in a position to make any statement. The claims to dental benefit sanctioned by all approved societies in the year ended June, 1927, were estimated at 1,100,000, and the cost at £2,500,000.

**Food Poisoning.**—On November 22nd Sir K. Wood said that the Minister of Health was aware that food poisoning had occurred in the Bath and Bristol districts last August. These cases, and other cases of poisoning by similar organisms, had been investigated by officers of his department and others, but the Minister was advised that in the present state of knowledge it was not always possible to safeguard against the infection of food by them. Further research was being made into the matter, and in the meantime the statutory provisions and regulations dealing with the handling of food prescribed requirements as to cleanliness and protection from contamination in general.

**Lead Poisoning.**—On November 22nd Sir William Jowett on Hicks in reply to Dr. Graham Little, said that in pursuance of Clause 2 of the Lead Paint (Protection against Poisoning) Act 1926 he had made an order on November 14th which would have the effect of allowing women and young persons to be employed in the execution of wall or ceiling paintings or in any similar work of

decorative design. He had been asked to receive a deputation to protest against the general prohibition in the Act against the employment of women in painting buildings with lead paint and to press for legislation for the removal of this prohibition. Seeing however that the prohibition was enacted by Parliament after full discussion recently as 1926 and that leave was refused in July last by the House of Commons for the introduction of a bill to remove the prohibition, he was not prepared to re-open the question and could not accede to the request.

**Indian Medical Service.**—On November 21st Earl Winterton stated in reply to questions (1) That at a test held last August in India to select candidates for permanent commissions in the Indian Medical Service only those holding an English degree were successful. It was not the case that instructions had been issued by the Secretary for India that the candidates who possessed Indian medical qualifications alone were unfit for permanent commissions in the Indian Medical Service and that an English degree was necessary. Candidates who possessed the necessary qualifications prescribed by the regulations whether obtained in India or in this country were selected strictly on their merits. He was not aware of any definite recommendation made by the committee on Indian students on this subject. Every effort was being made to improve the standard of medical teaching in India. (2) That recruitment for the Indian Medical Service was carried out strictly on the ratio of two Europeans to one Indian. This in present conditions had the effect of increasing the number of Indians in the Service. All officers drew the same rates of pay but those of non-Indian domicile received certain benefits to compensate for permanent service abroad. The additional expense in the case of the European officer was relatively small.

### Notes in Brief

No horses were used for experiments at the Porton Chemical Warfare Experimental Station during August, September and October. The Secretary for War considers that experiments with animals are essential at this station.

The area of opium poppies under cultivation in British India in 1926 was 17,657 acres.

The Home Secretary does not favour the introduction of a bill next year to do away with the waiting period of three days in workmen's compensation cases.

In the year ended July 3rd 1927 £24,970,000 was collected in health insurance contributions and the total income of the National Health Insurance scheme was £37,100,000. Expenditure in the same period is estimated at £39,500,000.

The Minister of Health does not think that further investigations into the effect on health of the noise from motor traffic would be of advantage.

## Medical News.

THE late Dr. Adrian Stokes, Sir William Dunn Professor of Pathology at Guy's Hospital, who died in September last from yellow fever contracted in the course of his researches at Lagos, Nigeria, has left estate of the gross value of £13,511. He bequeathed £10,000 to Geoffrey William Rake of Guy's Hospital, which he hoped might be of assistance to him in carrying on his research work.

THE Right Hon. Neville Chamberlain, M.P., Minister of Health, will open the Redhill Hospital, Edgware, on Monday, December 5th, at 2.30 p.m.

THE Fellowship of Medicine and Postgraduate Medical Association announces that Mr. Chapple will give a lecture entitled 'Practical hints in gynaecology and obstetrics' on November 28th, at 5 p.m. at 11, Chiswick Street. Dr. Parkinson will give a clinical demonstration at the National Hospital for Diseases of the Heart at 2 p.m. on December 2nd, both are open to all members of the medical profession without fee. From November 23rd to December 3rd there will be a postgraduate course in proctology at St. Mark's Hospital, fee £3 3s. The West End Hospital for Nervous Diseases is holding a course in neurology at 5 p.m. each afternoon until December 17th. The only other special courses this year are a fortnightly instruction from December 5th to 17th. On this will be held at the Infants' Hospital, Vincent Square, Westminster, every afternoon from 2.30 p.m. fee £3 3s. The other in dermatology will take place at the Hospital for Diseases of the Skin, Blackfriars, at 2.30 p.m. each day, fee £1 1s. After these two courses there will be a pause until the special courses for 1928 begin on January 9th. There is always however a general course of work which continues throughout the year and which may be started at any time. Tickets of admission to the forty London hospitals associated with this course may be obtained for any period from one week to one year. This is quite separate from the special courses though in certain circumstances it is an advantage to the postgraduate to take both concurrently. All information may be obtained from the Secretary of the Fellowship of Medicine, 1, Wimpole Street.

THE bi-weekly lecture demonstrations arranged for next month by the West London Hospital Post Graduate College include two by Dr. Harold Pritchard who on December 6th will deal with diabetes mellitus and on the 15th with intravenous treatment. On December 7th and 14th Mr. Donald Armour will discuss head injuries.

THE Royal Sanitary Institute is conducting a course of lectures and demonstrations in smoke inspection. The lectures are intended primarily for inspectors who are to be engaged in carrying out the provisions of the Public Health (Smoke Abatement) Act of 1926 which came into operation on July 1st last. The lectures at the Institute's house, 50, Buckingham Palace Road, S.W.1 which are being given on Fridays and Mondays, cover much ground in connexion with fuels, furnaces, chimneys, stoking, and the prevention of smoke. Demonstrations are also available at several works and institutions, including a Metropolitan Asylums Board Hospital. The Institute holds examinations in smoke inspection in London and at various provincial centres. The course is open to anyone interested in smoke abatement.

MAJOR TRYON, the Minister of Pensions speaking at the annual dinner of the Brighton and Sussex Medical-Chirurgical Society on November 19th emphasized the value and importance of the services rendered to his Department by the medical profession. He said that much pioneer medical work had been performed by and through the Ministry including the establishment of hospitals for borderline mental cases before the recommendation of the Royal Commission on Lunacy had been published. With the discovery of insulin special wards were at once set apart in one of the Ministry's hospitals for the immediate provision of this treatment, and similarly recent developments in the use of ultra-violet light were applied for the benefit of pensioners. The Ministry had recently sent a surgeon to the Continent to investigate the treatment of varicose veins by nerve surgery. After referring to the Ministry's provision of institutions for particular kinds of treatment, with special reference to mental deficiency and wounds of the skull, brain and chest, Major Tryon alluded to the high degree of perfection reached in the manufacture of artificial limbs and appliances and added that at the present time 3,570 beds were still required in hospitals belonging to the Ministry and treatment was provided for 5,250 out-patients. In regard to the medical work generally Major Tryon said: 'The gist of the matter is that whenever and wherever medical science has produced or even hinted at a better way of treatment a more accurate test in diagnosis or a new way of regarding any aspect of disease the Ministry has at once inquired, tested and adopted it if thereby any benefit to the pensioner might accrue. In pursuance of this policy we have kept in close touch with the heads of the medical profession. In 1919 a special committee was appointed by the Presidents of the Royal College of Physicians and the Secretary of the Medical Research Council to advise the Minister on the most effective way of dealing with his medical problems. At the same time we have everywhere done our utmost to co-operate with the private practitioners and the local hospitals. In short we have endeavoured to effect what is the ideal combination for public work—a co-operation of the whole time medical officer, specialist or administrator with the independent consultant and the general practitioner.'

THE autumn dinner of the Irish Medical Schools and Graduates Association was held at the Savoy Hotel on November 17th when Sir William de Courcy Wheeler presided over a large assembly of members and guests including Major General Sir William Hickie, K.C.B. Dr. Lindsay Rice proposed the toast of The Guests and Sir William Hickie in reply referred to the deeds of Irish regiments during the war and paid a special tribute to the medical officers. Sir Bruce Brice Porter and Dr. William Hill also responded. In replying to the toast of The President and Association proposed by Dr. Frederick Spicer, Sir William Wheeler emphasized the importance of keeping Irish medical practitioners together and congratulated the responsible or the increasing popularity of the association. He referred to the satisfactory establishment of an Irish Medical Council and to the abolition of administrative procedure together with the provision of administrative procedure to protect medical appointments from undue influences. The annual meeting and festival dinner of the association will be held in London on March 17th next. Applications for membership should be sent to the honorary secretary, Dr. F. P. Holmes-Merrick, 59 Kensington Court, W.8.

THE King has appointed Dr. Percy James Kelly (Surgeon General, British Guiana) to be a member of the Executive Committee of the Colony of British Guiana for a further period.

THE centenary of the birth of the well-known chemist, Marcellin Berthelot, has recently been celebrated in Paris.

**VACANCIES**  
**NOTIFICATIONS** of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 36, 37, 38, 39, 42 and 43 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 40 and 41.  
 A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 211

## An Address

ON

## SURGICAL CONVALESCENCE

DELIVERED BEFORE THE MANCHESTER SURGICAL SOCIETY  
BY

CHARLES ROBERTS, M.B., B.S., F.R.C.S.,

SURGEON MANCHESTER ROYAL INFIRMARY PRESIDENT OF THE SOCIETY

It is especially in war time that the problems of convalescence are most clearly perceived, and it was during a period of the war in which part of my duty was to inspect medically a group of Red Cross convalescent hospitals that the importance of convalescent treatment impressed itself on my mind and I determined to devote more attention to the follow-up and after-care of surgical patients.

Since that time it has been my practice at the Manchester Royal Infirmary to devote a part of one morning each week to seeing patients who have been discharged from my wards. All patients on leaving hospital are given cards and are instructed to attend and a record is kept of their progress and of the final result of treatment. In many instances one attendance suffices, in others repeated visits are made. For example after operations for gastric and duodenal ulcers patients attend every three months during the first year and at intervals of six months during the second year. This practice has been a source of much interest and many lessons have been learnt.

There is little doubt that surgeons are tempted to concentrate too much on the operations themselves. We live in an age of speed. Operations are becoming more and less standardized and patients are discharged as soon as possible often to be lost to the surgeon for ever. But the human body is not a mere machine and the hospital is not comparable to a loud factory. Surgery is something more than the mechanical side of medicine, and the operation is but one therapeutic measure in the treatment of the patient. As one surgeon has said 'Any operator of experience can perform a gastro-jejunostomy but it takes a surgeon to know how to remove a tube from an empyema.' It may be true that the better the operating the less will be the need for after treatment, and many of our patients will do well if left alone but many will be restored to complete health more comfortably and more quickly by proper after care and some of them will prove failures from want of it. Operative technique has attained a high stage of perfection and great improvement has been made in pre-operative preparation and immediate post-operative treatment but the convalescent stage has not received the attention it deserves. The contemporary literature is extraordinarily scanty. I submit that the whole subject requires more scientific investigation. Our attitude resembles too much that of the ancients as illustrated in the writings of Plato, who said

In all well ordered states every individual has an occupation to which he must attend and has therefore no leisure to spend in continuously being ill. Thus we remark in the case of the artisan, but ludicrously enough do not apply the same rule to people of the richer sort. When a carpenter is ill he asks the physician for a rough and ready cure an emetic or a purge or a cautery or the knife—these are his remedies. And if someone prescribes for him a course of diuretics and tells him that he must sweat and saddle his head and all that sort of thing he replies at once that he has no time to be ill and that he sees no good in a life which is spent in nursing his disease to the neglect of his customary employment and therefore bidding good bye to this sort of physician he resumes his ordinary habits and either gets well and lives and does his business or if that fails he dies and has no more trouble.

I have recently undertaken an inquiry into the duration of convalescence and the symptoms that arise between the time of leaving hospital and of return to light work or full occupation. 825 letters were sent out to male patients who had been operated on in the Manchester or Royal Infirmary for gall stones, duodenal ulcer, chronic appendicitis, inguinal hernia and hemorrhoids. 630 replies were received and 130 of these were discarded as the replies were unsatisfactory. Letters were dispatched in batches until 100 satisfactory replies had been received from cases of each operation. The results are shown in the table.

TABLE I—Average Duration of Convalescence after certain Operations

Time	Gall Bladder	Duodenal Ulcer	Appendix	Hernia	Hemorrhoids
Under 25 days	1	1	2	7	25
25 to 50 days	12	10	23	4	53
50 to 100 days	37	45	41	43	0
Over 100 days	40	33	50	27	4
Still doing light work	10	6	1	4	—
Total	100	100	100	100	100

The occupational classification in Table II is based on the two groups of indoor workers and outdoor workers, light and heavy work in each section forming a separate class. Class A contains those engaged in heavy outdoor work—carters, labourers, colliers, blacksmiths, bricklayers,

TABLE II—Average Period of Convalescence in Relation to Occupation

Occupational Class	Age	Return to Normal Work	Return to Light Work	Period of Light Work	No. of Cases
<b>I Gall Bladder</b>					
Class A	45.4	19.5	28.5	51.2	12
B	45.4	110.3	31.4	33.3	9
C	50	91.5	21.4	1.5	13
D	44.7	113.3	9.2	14.3	5
Average	45.9	115.4	—	—	39
9 still doing light work. 1 unable to work. (10=10)					
<b>II Duodenal Ulcer</b>					
Class A	41.5	143.4	34.4	47.5	20
B	33.4	112	9.9	21.6	9
C	40.1	125.1	4.5	25.7	22
D	33.9	72.3	17	17.9	7
Average	39.7	115.2	—	—	91
6 still doing light work. — unable to work. (6=100)					
<b>III Appendix</b>					
Class A	34.5	119.3	49.5	91	10
B	40.9	105	21.5	15.7	23
C	32.8	105.3	4.5	21.3	30
D	30	85.5	7.8	10.8	9
Average	34.5	104	—	—	69
1 still doing light work. — unable to work. (1=100)					
<b>IV Inguinal Hernia</b>					
Class A	8.3	16.1	2.3	32.2	9
B	29.5	56.8	23.5	12.7	10
C	35.2	83.5	2.8	3.6	23
D	30.1	75.6	16.5	19.5	23
Average	34.5	8.2	—	—	65
4 still doing light work. — unable to work. (4=100)					
<b>V Hemorrhoids</b>					
Class A	43	4.7	8.5	8.7	25
B	43.3	35	3.6	2.8	18
C	38.9	4.2	4.8	1.9	33
D	38.4	47.7	9.9	5.3	27
Average	40.9	9.9	—	—	103

Class B, light outdoor work—tram guards, tram drivers, police constables, motor drivers, printers, postmen, Class C, heavy indoor work—fitters, engineers, joiners, stokers, Class D, light indoor work—shop assistants, tidemen, clerks, professional workers. In each instance the period of convalescence is reckoned from the date of operation, not from the discharge from hospital.

TABLE III—Results of Operations as Manifested by Percentage Return to Work

Disease	Average Age	Returning Direct to Full Work	Returning via Light Work	Still Doing Light Work	Complaining of Symptoms
		Per cent	Per cent	Per cent	Per cent
Gall bladder	45.9	62	28	10	21
Duodenal ulcer	39.7	61	33	6	28
Chronic appendix	34.5	73	25	1	37
Inguinal hernia	34.5	58	38	4	20
Haemorrhoids	40.9	82	18	—	13

#### Symptoms noted after certain Operations

**Gall Bladder.**—After symptoms complained of in the gall bladder cases were recurrence of original symptoms one case flatulent dyspepsia, three cases, biliousness and pain in gall bladder area, one case, cramp-like or colicky abdominal pains with occasional diarrhoea, pain and neuralgia in the seat, pain and heavy feeling in the seat on exertion, weakness and bulging of the abdominal wall in the region of the seat, and general debility.

**Gastrojejunostomy.**—The symptoms complained of after gastrojejunostomy for duodenal ulcer were dyspepsia five cases, vomiting three cases biliousness one case, flatulence, four cases, symptoms as before operation one case, abdominal distension, one case pains in region of seat, one case, pain in the back, one case.

**Chronic Appendicitis.**—After operation for chronic appendicitis patients complained of pains in abdomen, eight cases, vomiting, four cases, flatulence two cases, biliousness one case, severe constipation three cases, looseness of bowels one case, pain neuralgia or stiffness in the region of the seat, six cases, sleeplessness and nervousness one case, pains similar to those before operation, one case.

**Radical Cure.**—After radical cure of inguinal hernia the symptoms arising were pain either aching or neuralgic, in the region of the seat, a feeling of weakness or dragging in the same area, stiffness in the surrounding muscle, and backache.

**Haemorrhoids.**—After the operations for haemorrhoids symptoms included impaired control of the bowel, two cases, loose swollen skin around the anus two cases, irritation or itching at the anus, six cases, feeling of fullness in the anal region, one case, rectal discharge, one case, rectal bleeding one case, severe constipation, one case, and pain in anal area, two cases.

E. W. Bridgman has published statistics on the duration of normal convalescence based on his experience at the convalescent section of a group of base hospitals during the war. In the camp graduated exercise under military discipline was carried out, whilst relaxation, both mental and physical, was carefully provided for. A follow-up system was instituted and it was ascertained that recovery was complete in more than 97 per cent of cases. To compare the duration of hospitalization of patients passing through the camp with those discharged directly to duty a group of records was obtained from the hospital centre of the period before the opening of the convalescent camp. No follow-up system had been instituted for these patients, but Bridgman states that he had seen some of those discharged return to the hospital for relapse, weakness, painful wounds, an inability to keep up, and, after long intervals, some returned with functional mental disorders. The following table shows the average stay in hospital and camp under the two systems.

TABLE IV—I Experience of Convalescent Camps

Diagnosis	No. of Cases	Average Stay in Hospital of Patients not going to Camp	No. of Cases	Average Total Stay in Hospital and Camp
		Days		Days
Haemorrhoidectomy	21	20	25	45
Hemiotomy	31	24	41	50
Hysterectomy	6	22	7	54
Tonsillectomy	10	20	8	37

He concludes that the average hemiotomy needs several weeks of cure before the patient is normal again, instead

of the three and a half that are commonly allowed, and he emphasizes the importance of graduated exercises and military discipline under real medical supervision in favouring and hastening convalescence. He states that the doctors and ward masters soon became adept in handling the occasional malingerer.

#### CONCLUSIONS

I think my investigation shows that the transition stage between serious injury, illness or operation, and normal health is undoubtedly an episode of very great significance and economic importance. Convalescence is not an intuitive process, but a definite state of illness in which arise minor ills and complications and deviations from the normal, and some of these may become fixed and serious. I doubt if operating surgeons sufficiently appreciate the shock and the prolonged effects of extensive operations. Moreover, the illness involves a change of habits and environment, and the patients suffer from the effects of enforced rest with its accompanying lack of exercise and deficient elimination. After the more serious cases convalescence is often as much a state of mind as of body. The wounds heal, but the patients are not themselves. All the organs are below the normal and nervous energy is diminished. They react excessively to any form of mental or physical stimulus. They tend to become introspective, and with this there may arise a state of nervous instability leading at times to hysteria and neurasthenia. Patients often suffer from various slight ailments such as dyspepsia, constipation, and the neuralgias, and occasionally the most prominent feature is sleeplessness. Our aim must be to get the patient to resume his ordinary habits as quickly as is consistent with safety. Some are in danger of relapse in their desire to go too quickly, and must be restrained from doing too much. Others require constant encouragement to enable them to make the progress desired.

Few patients have a clear idea of what their conduct should be after leaving hospital or nursing home. They are very largely influenced by groundless fears and by the advice of ignorant or too solicitous friends. The family physician, when consulted, is not always a reliable guide, from lack of knowledge of the individual case or unfamiliarity with the surgical aspects of the particular condition. It would be of immense help if all medical practitioners could follow up their patients to hospital, be present at any operation performed, and visit them occasionally afterwards. Opportunities for discussion as to after-treatment would then always be possible, and, in the transfer of medical responsibility from hospital control to that of the practitioner, continuity of medical care would not be lost. Failing this, I think it is incumbent on the surgeon to communicate directly with the practitioner when a patient is discharged from hospital, and give him all necessary information. Much help can be afforded the patient by the personal advice of the surgeon. The condition found and the nature of the operation should be suitably explained, and he should be reassured whenever possible as to the future. He should be warned of the possibility of minor symptoms that may arise during convalescence, and of the dangers that ensue from morbid introspection. Particular cases require special advice—for example, enormous help may be given by instruction in the management of a colostomy. Some patients must be compelled to live within definite limits after certain operations. This is notably so in abdominal disease, especially after operations for gastric and duodenal ulcers, gall stone operations, and when a condition of visceroptosis with intestinal stasis is present. In these instances I have found it most convenient to use printed charts of general instructions with special instructions as to diet.

The charts that follow are used in cases after operations for gall stones and duodenal ulcer.

#### INSTRUCTIONS AFTER OPERATION FOR GALL STONES

Take frequent small meals rather than heavy meals.  
Take a tumblerful of hot water night and morning.  
Take a drink of hot water at the end of each meal.  
Take salts in the morning once or twice a week.  
**Diet Allowed.**—Skimmed milk, Tea, Soups made with milk, Vegetables, Tapioca, Rice, etc., Cereals, oatmeal, etc. Fats, such as white margarine, butter, lard, etc. White meat and lean meat, boiled, grilled, or broiled.

of a St Potatoes mashed or in their jacket Turnips Spinach  
Artichoke Mild cheese Fruit a few three months  
Forbidden—Fat and cream Stewed and fried foods Sweetbread  
Liver Duck Kidney Pork Thick pudding Cane High or spiced  
fishes Only fish so for Murrings Salmon Sardine Cooked  
butter Pa Cablage Raw vegetable Strong cheese Aerated  
waters Alcohol

DIET AFTER CONVALESCENCE

Guide to Diet

- 1 Easily digested food
- 2 Large meals should never be taken
- 3 Preferably there should be no drinking during meal
- 4 Food and drink should not be taken hot
- 5 Eat slowly masticate thoroughly avoid bulky meal
- 6 One glass of milk between meal and not before retiring

*Breakfast*—Carefully made porridge Cream lightly boiled White fish  
boiled or baked Cocoa or weak tea with plenty of milk Cold dry  
toast and marmalade or butter Cold boiled ham

*Other Meals*—Omelette A little roast beef well cooked mutton or  
veal Calf's head Fried beef Chicken Tripe Spinach Cauli-  
flower Mashed potatoes Macaroni Milk pudding Junket Blane  
mango Custard

*Forbidden*—Fried fish in fat Smoked fish Bacon Sauage Meat  
pie Meat pudding Steak Made-up diet P-cooked meal  
Cabbage Bruised fruit Carrots Turnips Parsnips Watercress  
Fried potatoes Peppers Mustard Vinegar Pastry Cakes Brown  
bread Jam Sweets Cheese Coffee Alcohol

My investigations have shown that success or failure in the treatment of gastric and duodenal ulcers depends far more on proper after-care than the exact type of operation chosen. I am strongly convinced that the attitude of those surgeons who affirm that they have no use for any operation which does not completely cure the patient is entirely wrong. A change of air greatly assists the convalescence. He gets away from the environment of his illness. He sees new scenes and new people and gets new interests. Routine and regularity should mark the period. Each day should be mapped out with the proper intervals of rest and

graded exercise, and the amount of mental recreation should be apportioned. While it is difficult to estimate accurately the effects of post-operative respiratory exercises and physical exercises on the Swedish principle, there is no doubt that the general circulation is improved, the bodily functions are more normally performed, muscular weakness is diminished, and the patient returns to complete health more quickly. I hold strongly that systematic exercises should be a routine measure in the convalescent period. The various measures of physiotherapy also hold a high place in conducing to rapid recovery.

For the convalescent period the hospital patient or at home does not as a rule, provide an environment conducive to rapid recovery, and though many may be sent to convalescent homes, there will always be a large proportion of patients for whom it is not possible to provide accommodation in these institutions. I strongly believe that there should be a convalescent department attached to each hospital. In this way we should eliminate the neglected period that now prevails between the completion of active surgical treatment and the time of return to full occupation. To this department there could be attached a social service for it has been estimated that 30 per cent of patients discharged from hospital require help in this direction. The medical staff in charge should be specially trained in convalescence. Here patients would be completely investigated and graded their requirements as to diet discipline and physical and mental recreation would be determined and any disabilities that arose or whose presence had been overlooked could be dealt with and the malingerer eliminated. Advantage could be taken in many instances to improve the general health.

## THE RESULTS OF INSULIN THERAPY IN DIABETES MELLITUS\*

BY

HUGH MACLEAN, M.D., D.Sc., F.R.C.P.

Professor of Medicine St. Thomas's Hospital University of London

ABOUT four years have elapsed since insulin became generally available in this country for the treatment of diabetes mellitus. This is not a very long period in which to judge the ultimate effect of insulin on diabetes, but it is sufficient to enable us to come to some definite conclusion as to its more immediate and direct influence on the disease. The theoretical considerations which govern the action of insulin in diabetes are quite clear. The oxidation of our food-stuffs requires the presence of a substance which is normally supplied by the pancreas. When for some reason the specialized pancreatic islet cells fail to supply this substance in the necessary amount, an interference with the burning up of sugar and fat results. This is the basis of diabetes mellitus. Since it is now possible to supply this essential substance in the form of insulin, it might be thought that the treatment of diabetes should no longer present any difficulties, and that all that is necessary is to supply sufficient insulin to make up for the deficiency in any particular patient.

The difficulty, however, is to supply the exact amount of insulin necessary for the varying requirements of the organism. In the body there is a mechanism which regulates the production of insulin in accordance with the tissue needs at any given time. The amount of insulin required by the body is dependent on many factors and varies under different conditions. The artificial use of insulin by injection is attended by the drawback that we cannot regulate the amount required to supply the exact demands at any given time. It is true that in some patients we can get fairly close to the theoretical needs, but this can only be accomplished by paying great attention to

various factors such as diet and exercise. Often it is impossible to regulate the artificial supply of insulin so as to simulate the normal mechanism. Though we can now supply the necessary insulin when the body can no longer secrete it, we can so far do but little to reproduce the results of the normal automatic mechanism which regulates the production of insulin according to the prevailing needs at the moment. This is one of the main difficulties in insulin therapy, but under ordinary conditions this drawback can generally be more or less overcome. It is when diabetes becomes complicated by various infections, that our troubles really assume a serious aspect. In certain of these conditions insulin seems to lose its normal activity, and in spite of greatly increased dosage the patient may sometimes succumb. The healthy individual suffering from a similar infection usually shows no disturbance of metabolism such as is seen in diabetes, and it must therefore be assumed that insulin when supplied naturally by the body tissues is more effective in these conditions than it is when given artificially by injection. Indeed, in certain cases of diabetes complicated by severe infection, insulin artificially administered proves of little or no benefit.

Before considering the effect of insulin in diabetes it will be necessary to consider the results obtained by diet in the days before insulin was available.

### Result of Dietetic Treatment of Diabetes

For some years before the isolation of insulin much attention was paid to the dietetic treatment of diabetes, and many claims were made on behalf of this method. While it was generally agreed that the only means of inflicting the disease in any way was by means of properly regulated diet, the outlook for the average patient suffering from the disease was gloomy in the extreme. Generally it was found that suitable diet had a wonderful effect to begin with, but in spite of the greatest care the patient after a time gradually began to show his old symptoms, and soon a point was reached at which the dietetic measures no longer prevented the occurrence of severe glycosuria and ketosis. From this point the patient usually went steadily downhill and soon coma or some intermitted infection terminated the scene. The duration of life under dietetic treatment depended, of course, on the

\* A paper reading a discussion in the Section of Medicine at the Annual Meeting of the British Medical Association, Edinburgh, 1917.

severity of the lesion, but, unfortunately, as it is generally seen in young people, the disease is a steadily progressive one, and after a time its course cannot usually be stayed to any appreciable extent by diet.

No doubt so-called diabetes in elderly subjects often presented an entirely different picture, and frequently responded well to diet. In such patients, however, glycosuria is the main feature, and there is generally little or no ketosis. In many of them no evidence of disturbed oxidation can be obtained, and the patient may suffer little or no inconvenience. This type of case is really not a true diabetes, but a simple glycosuria which is probably dependent on an inability on the part of the liver and muscles to store sugar in the normal manner. Consequently hyperglycaemia results, and sugar is passed in the urine. The usual symptoms of diabetes are absent, or, if present at all, are of a very mild nature. These cases should not be classified as true diabetes, there is no tendency to coma, and the glycosuria can often be controlled by dietetic measures. Not infrequently the sugar is detected as the result of a routine examination of the urine. Often the glycosuria does no harm whatever to the patient, and though the condition may sometimes develop into a true diabetes, yet, in my experience, this is a comparatively rare sequel. Such cases do not come under the heading of true diabetes.

In considering the results of dietetic treatment it is essential to remember the difference between these two types, for the ultimate effects of diet depend almost entirely on the nature of the cases treated. Elderly patients suffering from glycosuria with little or no ketosis frequently do exceedingly well on diet. Patients suffering from true diabetes ultimately do very badly, though the results may be satisfactory for a short time. The success or failure of dietetic treatment, as indicated by the experience of any particular observer, depends very largely on the number of cases of ordinary glycosuria he includes under the term "diabetes." If many of the patients were suffering from nothing more serious than the well known glycosuria of the elderly individual, then dietetic treatment may appear to give excellent results. When, on the contrary, only cases of true diabetes with the usual symptoms are included, the results of diet are absolutely unsatisfactory in the great majority of patients.

When considering the effects of insulin, it is really with diabetes as it shows itself in its typical form that we have to deal. Usually diabetes is a disease of youth or of middle age, though not infrequently it may be seen in old age. On the whole, true diabetes is more common in patients under 45 years of age, while glycosuria due to lack of storage generally occurs after this age. In arriving at a definite conclusion as to the effects of insulin in diabetes it is necessary to bear in mind that it is its beneficial effect on true diabetes that is really important. In the other class of case coma does not intervene, and death is usually due, not to the effects of the glycosuria, but to some other disease.

Before the days of insulin many observers claimed excellent results from dietetic treatment. Others frankly confessed that diet, however carefully followed by the patient, was quite useless after a short time. Several years ago I carefully examined my figures for patients suffering from typical diabetes who were treated by dietetic measures. The results showed that death took place on an average in about five years or rather less after the dietetic treatment began. I have had communications with various authorities in other countries on this subject, and the information I obtained was to the effect that the average duration of life in patients on dietetic treatment was from four to six years. These cases, of course, did not include patients suffering from glycosuria without ketosis. We may, therefore, take the view that any patient suffering from diabetes in the true sense of the term is unlikely to survive for more than five or six years on an average when the treatment is restricted to dietetic measures. Indeed, in severe cases, two to three years is often all that may be reasonably expected. Consideration of these figures will enable us to appreciate the changes brought about by insulin therapy.

### The Results of Insulin Therapy

In the four years that have elapsed since insulin became generally available for the treatment of diabetes 291 patients suffering from typical diabetes have been treated in a special clinic in the Medical Unit of St Thomas's Hospital. All these patients showed definite ketosis, and the majority of them were young or middle-aged. Cases of ordinary glycosuria without ketosis are not included in this list. Each patient was first treated as an inpatient in the ward, the diet and insulin dosage being carefully worked out. After being discharged from the ward the patient attended the clinic at definite intervals. As an out-patient he was usually being looked after by his medical practitioner. When any change in diet or in insulin dosage was considered advisable, the practitioner was informed of the result of the examination, and the suggested changes indicated to him. The complete treatment of the case, however, was, as far as possible, controlled by the special clinic. The following figures show the results of insulin treatment of these cases up to date. In this connection I should like to thank Dr Crozier of the medical unit for his help in keeping records of these cases and for assisting me in compiling the results.

Year of admission of patient	No of patients admitted.	No of deaths to date.
1923-24	77	5
1924-25	76	2
1925-26	68	3
1926-27	70	2
Total	291	12

Several of these patients were admitted in coma, three of them developed coma on three different occasions and a few more were in coma on two occasions. All these patients are now doing well. Two patients with tubercle bacilli in their sputum are still alive and in fairly good health.

Of the twelve deaths, one, a girl of 19, developed coma outside, and was treated by her local doctor. Another was treated in hospital, but was admitted at a rather late stage, and though apparently a case of uncomplicated diabetic coma, she failed to respond to insulin. Three of these cases recovered from coma, but died of cardiac failure. In all the others coma developed as the result of some such complication as influenza, pneumonia, or septic lesion.

These figures show a death rate of almost exactly 4 per cent. As they were all well marked cases the figures indicate a very extraordinary improvement over the results of dietetic treatment. Judging from the death rate prior to the use of insulin, the average number of deaths in these 291 patients would have been much greater if treatment had been restricted to diet alone. While it is quite impossible to give anything like exact figures, it is nevertheless possible to arrive at some probable conclusions as to what would have happened if no insulin had been used in these cases.

If we take six years as the average duration of life on diet alone, it appears that of the 77 patients admitted in 1923-24 at least half of them would now be dead. Taking everything into consideration, it seems probable that more than one-third of the total number of these 291 cases would not be alive now. In addition to the above patients, I have seen a fair number regarding whom I have no definite statistics. The general impression conveyed, however, is that the average results of insulin treatment were somewhat similar. So far, I have only seen one diabetic patient who failed entirely to respond to insulin administration. As no post-mortem examination took place in this case it is possible that some other complication was present.

These results point to the conclusion that practically all uncomplicated cases of diabetes in young or middle-aged people can be controlled by the judicious use of insulin. It must also be remembered that the general physical condition of diabetic patients treated by insulin is altogether different from that which obtained under dietetic treatment. In many cases dietetic treatment was so severe that the patients could not be induced to continue with it. Some of them quite frankly stated that they preferred death to the physical agony which they

endured. In almost all had cases the period of a year or so preceding death was usually not distressing and hopeless. Now all is changed. The disease which was formerly so grave has been shorn of many of its terrors, and, in my opinion, it ought to be possible to control any ordinary case of uncomplicated diabetes and to restore the patient to a fair degree of health and comfort.

#### *Some Difficulties encountered in the Use of Insulin*

In uncomplicated cases of diabetes insulin has proved to be a very excellent remedy. With a well balanced diet and suitable dosage of insulin patients usually get on all right and give little trouble as long as infections of various kinds are avoided. When a diabetic patient becomes ill from some acute disease it often happens that the insulin loses its effect to some extent and a marked tendency to coma sets in. In these circumstances the insulin dose must be very materially increased, perhaps to three or four times what the patient was having previously. Sometimes even much larger doses than this are necessary for a time. The secret of successful treatment of diabetes by insulin lies largely in a recognition of this fact. It cannot be too strongly emphasized that very large doses of insulin may be required when acute infections supervene. Very often unfortunately, the medical man in attendance on the patient takes the view that some temporary complication which perhaps makes the patient unable to take his ordinary diet indicates a decrease in the dose of insulin. Such treatment is often fatal. The dose of insulin should in the great majority of these patients be increased at an early stage of the complication. When this is done in a judicious manner it is my experience that grave consequences can very often be avoided. No doubt the complication itself may sometimes kill, irrespective of the diabetes, but probably the most essential point to bear in mind in the routine treatment of diabetes by insulin is the necessity to give a sufficient amount of insulin when complications supervene.

#### *The Results of Insulin Therapy in Young Children*

It is well recognized that diabetes in the child is a very serious condition and, in the absence of insulin, is liable to prove fatal in a very short time. On the other hand the disease is usually well controlled by insulin when a sufficient dose is given. Since nearly all children contract some of the various ailments common to children at some time or other, it is obvious that in the case of very young people there are special difficulties and dangers to contend with. In my experience, however, these dangers are not nearly so formidable as they might appear to be. Undoubtedly very great care is necessary, and the dose of insulin must at once be increased when the onset of any of these ailments is accompanied by an increase in the diabetic symptoms. When this is carefully done the results on the whole are good. I cannot claim to have seen very many cases of diabetes in young children, but since 1923 I have treated over thirty children varying in age from 2½ to 10 years, and all of these are alive to-day and in quite good health. We have not had a single death from diabetic coma in a child under 10 years of age. Many of these children were first seen while in coma, and a few of them developed coma on at least two subsequent occasions. Some of them have contracted and safely weathered such infections as whooping-cough, measles and chicken-pox. While it must be admitted that the outlook from the theoretical point of view is not good in the case of children, practical experience suggests that the young diabetic can very often be safely guided through the storms which are peculiar to childhood, and that very satisfactory results can often be obtained.

An interesting question arises in connection with the possible cure of diabetes by insulin in the young. Definite evidence has been brought forward that regeneration of the islet cells of the pancreas may take place in a young diabetic when the disease is controlled by insulin. From this it might be argued that the administration of insulin in very young people might sometimes effect a cure by allowing new pancreatic cells to develop. Several of my cases, however, require much smaller doses of insulin than they did at the earlier stages of treatment, but

I have not yet seen a single patient whose recovery of tolerance was sufficiently marked to enable him to discard insulin. In some of these young patients there has been so sign of increased tolerance and the amount of insulin had sometimes to be increased as the child grew older. It seems fairly certain that all these children will find it necessary to continue the administration of insulin throughout life. It is quite certain that the lives of many children who would otherwise die of diabetic coma can be saved by insulin, and that the outlook is not necessarily as bleak as it is sometimes considered to be. Given a child otherwise healthy, there is really good ground for the view that such a child may reach adult life, and be no worse off than the average patient in whom diabetes first showed itself at a much later stage in life.

#### *Insulin in Elderly and Old Patients*

In old patients, as already indicated, true progressive diabetes with ketosis is not very common, though it is certainly met with from time to time. By far the most frequent condition in these patients is the type of glycosuria already discussed. In an uncomplicated case of diabetes in an elderly patient insulin appears to act as well as it does in the young or middle-aged but, unfortunately, it often happens that other ailments are present. In these circumstances good results could hardly be expected in general from the use of insulin in old patients, and this is in accordance with experience. Insulin, however, often gives excellent results in many old people who have glycosuria with such symptoms as weakness, neuritis and local irritation, but whose condition is otherwise good. It all depends whether the lesion is or is not complicated with degenerative diseases and other changes incident to old age. There is obviously an absence of the recuperative power of the young individual, and allowances must be made for this.

#### *The Use of Insulin in Surgical Conditions Complicating Diabetes*

Insulin has revolutionized diabetic surgery. Before insulin was available the surgeon hesitated as a rule to incur the grave risk associated with an operation on a diabetic patient. In desperate cases when an operation had to be attempted, complications often supervened and the patient died. Since insulin has become available for the treatment of these patients, it is safe to say that under good conditions, and when treated by someone who understands the use of insulin, the diabetic has about as good a chance as a normal patient who undergoes an operation. This is well borne out by the statistics of the Mayo Clinic. In 657 operations performed on diabetic patients only 20 deaths occurred. Taking into consideration the fact that many of these patients were suffering from arterial sclerosis and other degenerative lesions the results appear to be very satisfactory.

#### *Some Anomalous Statistical Results*

From the excellent results obtained by the use of insulin it might be thought that diabetes would figure no longer in official statistics as an important cause of death. At any rate, it might be considered that the number of deaths officially returned as caused by diabetes would be much reduced, and that this reduction would continue for several years. Since the majority of diabetic patients develop the disease when comparatively young, the natural inference would be that the lives of these patients would be prolonged for many years by insulin ultimately, when death took place in the usual course of events, though the patient might die of something quite different from diabetes, there would be a tendency on the part of the medical man to return the cause of death as diabetes. Theoretically, then, there should be a marked diminution in the number of deaths from diabetes for several years, while after a certain period an increase might be looked for, but the majority of the deaths should be those of elderly people.

So far as official statistics go, however, insulin has apparently not decreased the number of deaths from diabetes. According to these returns, insulin has failed to affect to any material extent the death rate from diabetes. We are therefore faced with the curious result

that apparently the number of patients dying from diabetes is as high as ever, in spite of the undisputed fact that many lives are saved by insulin. What is the explanation of this? One possible explanation might be that the incidence of diabetes has largely increased during the last few years, and that, despite the beneficial action of insulin, the increase of the disease is so marked as to keep the death rate up to the old level. This view really means that in the absence of insulin the death rate from diabetes would be very materially higher than it now is. Against this view is the fact that insulin is such a potent measure in the treatment of uncomplicated diabetes that even a marked increase in the incidence of the disease should not materially increase the death rate. There appears to be some evidence pointing to the conclusion that there is a tendency for some slight increase in the number of diabetic cases, but this does not explain the difficulty.

An examination of the age of death reveals the fact that the age incidence has shifted, and that for the last few years the majority of diabetic deaths occurred in elderly people. The number of diabetic deaths in young people has very materially decreased. Now, since true diabetes is comparatively rare in elderly people, while simple glycosuria is exceedingly common, it is but reasonable to suppose that the majority of persons returned as having died from diabetes really suffered from simple glycosuria. Since this type of glycosuria does not as a rule produce coma, it is more likely that the majority of these deaths were caused by some condition other than diabetes. The fact that glycosuria happened to be present resulted in "diabetes" being returned as the cause of death. No doubt the recent introduction of insulin has tended to focus attention on glycosuria, and so its presence is more frequently determined. Glycosuria, when present, is such a definite symptom that naturally it would nearly always be mentioned under the term "diabetes" in the official certificate of death.

Again, it is certain that insulin is often not nearly so effective in the treatment of coma in the elderly as it is in the young. Coma is exceedingly detrimental to the heart, and since the heart muscle in old people frequently suffers from some degree of degeneration, it is not unusual for the patient to recover from coma and to die of cardiac failure.

All these facts may play a part in explaining the anomalous official figures which apparently suggest that insulin has failed to reduce the diabetic death rate. These considerations indicate the marked importance of differentiating between cases of true diabetes and those of simple glycosuria.

#### *Results of Insulin Treatment in Coma*

When coma has actually developed much depends on the quickness and energy of the medical man in attendance. The patient should be treated at the earliest possible moment, for the strain on certain of the organs, such as the heart and kidneys, is very great, and, if prolonged, may result indirectly in death.

If the patient is seen at a fairly early stage and no complications are present, recovery should be the rule. I have not had a single death from coma in a young and otherwise healthy patient since insulin became available. In patients suffering from acute infections recovery is more doubtful, but if sufficient insulin is used a successful result should be frequently obtained. Generally speaking, the young diabetic patient, healthy in other respects, should not die from diabetic coma if insulin is judiciously administered at an early stage. In old people the case is very different, for reasons already discussed. Coma in a vigorous sound patient generally responds to insulin, whatever the age happens to be.

#### *Some Points in the Treatment of Coma*

It is generally agreed that the most important measure in the treatment of coma is to give insulin in sufficient amount at the earliest possible moment. Whether or not this should be combined with the administration of sodium bicarbonate is a matter on which opinion is divided. From some experiments carried out in my laboratory by Dr Goldblatt, it would appear that the use of alkali, at any

rate in large doses, is definitely contraindicated in diabetic coma. Goldblatt induced a ketosis in himself by starving for forty-eight hours. At this stage the urine contained fairly large amounts of acetone and diacetic acid, as indicated by Rothlie's reaction and the ferric chloride test. This ketosis rapidly disappeared after taking some glucose. Careful observation showed that after the ingestion of 50 grams of glucose dissolved in water the ketosis disappeared entirely in almost exactly one hour. When, in addition to the glucose, a large dose of sodium bicarbonate was also taken, the ketosis persisted for a long time, and was still present in definite amounts after eight hours. Many experiments of a similar kind were carried out, both on man and on animals, the results were always the same, and tended to show quite conclusively that sodium bicarbonate administered in the course of an acidosis markedly prolonged the condition. In the light of these experiments there can be little doubt that the ingestion of large doses of alkali during diabetic coma tends to hinder the disappearance of the coma. Sodium bicarbonate should, therefore, not be given when treating coma by insulin, since it does no good and definitely retards recovery.

#### *Insulin Treatment and the Persistence of Glycosuria*

It might be thought that the results of insulin therapy in any given patient would depend on keeping the blood sugar normal and the urine free from sugar. Experience shows quite definitely that this is not always so. While it is good practice in all cases to endeavour to render the patient aglycosuric, yet it may sometimes be impossible to do so without having recourse to very frequent injections of insulin. In my experience patients whose blood sugar was kept within normal limits at all times, and whose urines were constantly free from sugar, did no better than others whose blood sugar could not be always kept low. In the case of a small boy under my care it was quite impossible to control the blood sugar and glycosuria, for this patient had a real genius in the way of procuring all sorts of prohibited food. While in hospital it was almost impossible to regulate his diet, and after going out he was entirely beyond control. His urine nearly always contained a large amount of sugar—sometimes a very large amount—which generally depended on liberal supplies of chocolate which he bribed his young friends to procure for him. He seemed a quite hopeless case, and I must admit that I anticipated disaster, yet in spite of all he has done quite well and is now well developed, vigorous, and healthy. Indeed, the result in the case of this young patient makes one wonder whether certain of our theories connected with the treatment of diabetes are sound. Certainly it is best to keep the urine free from sugar, and the blood sugar as near the normal as possible, but the medical man need not despair if he finds this ideal difficult. Many patients do exceedingly well even when some glycosuria is more or less constantly present.

#### *The Administration of Insulin*

Insulin is usually given twice daily—in the morning before breakfast and at night before the evening meal. In some patients two doses are not sufficient to keep the blood sugar within normal limits, and the question arises whether in such cases we are justified in giving three or more injections. I am quite definitely convinced that the injection of more than two doses usually does more harm than good. Though frequent injections may control the glycosuria, the mental effect is so disturbing that many patients cannot stand it. There is a feeling that they can never get away from injections for any period of time, and they sometimes suffer from a definite nervous condition. I have seen a patient in a hopeless condition of nervous dread as the result of the administration of insulin three times a day, all the symptoms disappeared when the patient was put on two daily injections.

#### *Diet and Insulin*

There is no doubt that the effect of insulin therapy is largely dependent on the balancing of the insulin dose with the diet. Experience, however, shows that, provided sufficient insulin is taken, there are fairly wide limits of

diet between which the patient can live and thrive. Many of our accepted ideas with regard to diet are theoretical, and do not always work out well in actual practice. When sufficient insulin is given it is quite possible for a patient to get along satisfactorily without weighing his food. Patients who are feeling fit as the result of insulin treatment are usually engaged in some business or manual labour and cannot be expected to carry a balance about with them. Indeed it is seldom, if ever, necessary to weigh the food constantly if the patient is at all intelligent. All that is required is to teach the patient to observe how much food is represented by a definite weight. After a very little practice he is able to select and gauge his diet with ease. The average patient very soon learns to eat approximately the same amount of food each day without weighing it, and I am beginning to think that the added comfort induced by this method results in the patient being in better condition than is the case when his food is scrupulously weighed out for him. The simpler we make all the arrangements connected with insulin therapy the better results we obtain, provided that the main principles are always kept in view.

On the whole, insulin can, in general control the symptoms of diabetes in uncomplicated cases. There are drawbacks to its use, but when judiciously administered it usually results in restoring the patient to a satisfactory state of health. This is especially so when insulin is used at an early stage of diabetes. So far no substitute has been discovered which can be taken by the mouth. None of the pancreatic mouth preparations at present on the market appear to have the slightest effect on the disease. In spite of the claims constantly advanced on their behalf Dr. Fulkner, who recently carried out an investigation on this point in my laboratory, came to the conclusion that there was no evidence of any action on carbohydrate metabolism as the result of taking these preparations.

The latest mouth preparation is a synthetic product called "synthralin." There can be no doubt that this substance when taken by the mouth does produce a definite effect in certain cases of diabetes. The glycosuria is lessened and the ketosis is often markedly reduced. The product, however, has marked toxic properties, and tends to produce gastro-intestinal and other disturbances so that its use in the treatment of diabetes is at present not practical. It is conceivable that some preparation of a somewhat similar constitution may be found which will have a similar action without the toxic effects of synthralin. Meanwhile we must accept the view that, for the present, the only useful substance in the treatment of diabetes is insulin.

## STATISTICAL EVIDENCE OF THE VALUE OF INSULIN

BY

THE LATE PROFESSOR K. A. PETTEN,  
University of Lund, Sweden

When we are dealing with a chronic disease we cannot come to a true knowledge of the prognosis merely by observation in the clinic. As regards diabetes we have all seen in the old days how many patients died from coma, and in this respect we have obtained a certain knowledge of prognosis, but full knowledge can only come from following up in a systematic way a sufficient number of unselected cases. Very few investigations of that kind have been made. I know of only two—one by Horace Gray in America the other by Milmo, using the material from my clinic. Milmo dealt only with patients after at least five years had passed since they were first treated in the clinic. The results of this investigation were that 70 per cent of cases showing a fasting blood sugar value of 0.18 per cent on admission ended fatally. The interest of these investigations is the greater because the doors to the country where we could get knowledge of this kind are now closed and no human force can open them, they were closed by

the discovery of insulin, and the noble war in which our colleagues in Toronto have given the fruits of the discovery to the whole world.

It will in time be of the greatest interest to compare the corresponding figures of the insulin period but the time for this is not yet ripe. Professor Moelne has given us his statistics for four years of the insulin epoch, and we must thankfully recognize that the figures speak for a very hopeful view on the prognosis of this disease, only the future, however, can give us the definite answer.

In the figures I am giving here of my cases during the insulin epoch I am for the present dealing only with cases which were admitted to the clinic with a clear picture of coma.

### Seventy-three Attacks of Coma in 5 Cases (May 1923 to July 1927)

Year	No of Cases	Living	Fatal Issue		
			In Coma		Other Disease
			In Hospital	At Home	
1923	10	6	—	—	4 (3 tuberculo sis)
1924	15	9	1	4	1
1925	10	10	—	—	—
1926	17	14	1	—	2 (scylla)
1927	5	3	2 (11)	—	—
Total	57	42	4 (7)	4	7

Analysing the cases of death in coma in the clinic, we find that in 1924 we had not formulated our present rules for treatment, and the patient who died in that year was treated with too small doses of insulin. The 1926 case and one of the 1927 cases were patients who had refused insulin treatment in the clinic earlier in the illness, in the other 1927 case the necropsy revealed a broncho pneumonia which the pathologist considered to be antecedent to the coma.

With regard to the treatment of coma it is my rule to try to bring down the blood sugar to a normal value in a very short time—twelve hours at longest preferably in six or eight, in my opinion it is unnecessary to wait for the report on the blood sugar before giving a further dose of insulin if the respiration continues to be increased a fresh dose of insulin may be given after half an hour's interval.

As to diet I agree with Joslin and give the same diet as in other cases of grave diabetes, consequently I give no glucose. Campbell in Toronto originally spoke in favour of large intravenous injections of glucose, I am glad to see that in his later publication he has abandoned this treatment and says nothing more about it. The following table gives the dates of the latest information about my cases.

For the 42 living cases the latest information is

From June 1927	9 cases
May 1927	17
April 1927	6
March 1927	6
February 1927	7

For comparison I give the corresponding figures of Joslin's cases from his latest publication.

### Joslin's Cases Sixty-three Attacks of Coma in 5 Cases (April 1923 to February 1927)

Year	No of Cases	Living	Fatal Issue		
			In Coma		Other Diseases
			In Hospital	At Home	
1923	11	8	2	1	—
1924	13	13	—	—	5
1925	1	12	—	—	2
1926	17	15	—	—	1
1927	3	2	1	—	—
Total	55 (53)	40 (31)	3	1	8

Joslin has not made a distinction between the number of attacks and the number of cases. I have had some difficulty there over, and I hope I have made no mistake in quoting his figures.

Communicated to the Section of Medicine at the Annual Meeting of the Fifth Medical Association at Edinburgh in a discussion on the results of insulin therapy in diabetes mellitus. New of Professor Petten's recent death reaches us as we go to press with this paper.

For Joslin's 45 living cases the latest information is

From	4 cases
February, April, 1926	9 "
June July, 1926	7 "
September, October, 1926	9 "
November, 1926	9 "
December, 1926	4 "
January, 1927	6 "
February, 1927	9 "
March, 1927	3 "
	45* (51)

It will be seen that Joslin's results—I am very glad to recognize it—are a little better than mine. On the other hand, his information from his patients is in part not so recent as mine, I hope that later information will not raise the number of his fatal cases.

That so many of our coma patients are still living is very creditable to them, the great majority are under observation in the out-patient department, and we know that they follow the advice given concerning diet very carefully. If we have deserved some credit for the result it is because we have used our influence in educating them, and the patients have understood that it was best for them to follow our advice.

A short time ago Dr. de Jong of Leyden sent me the figures of the mortality from diabetes in Holland during recent years, he had recently told me that there had been a great increase in the mortality from this disease. The figures, however, show, when divided into age groups, that the curve for the mortality for all ages below 50 takes a quite horizontal course, for the age period 50 to 64 also the curve shows no very evident rise but for the years after 64 the number of deaths from diabetes has increased during the years 1911 to 1926 about 200 to 300 per cent. It is quite evident that the enormous difference shown for the years 1911 to 1926 must be due to the attention now given to diabetes and the development of a more accurate diagnosis as to the cause of death in patients dying at a late age. This is the opinion that I have defended for many years to explain all those statistical differences which appear to indicate that the disease is increasing in frequency.

### CLASSIFICATION OF GLUCOSURIA FROM THE POINT OF VIEW OF INSULIN TREATMENT

BY

P. J. CAMMIDGE, M.D.

Most observers, including Banting (Nobel Lecture, 1925), are now agreed that, as I predicted on theoretical grounds in 1922, insulin is not a cure for diabetes. It is true that many diabetic patients exhibit a considerable recovery of carbohydrate tolerance after treatment with insulin, but similar recovery occurred as a result of the "fasting" treatment, and the cause is probably the same—namely, the physiological rest provided for an exhausted function, in the one case by viciously performing its work, and in the other by reducing the demands upon it to a minimum. There is, however, the important difference that in the fasting treatment the horse is starving while the grass is growing,\* whereas with insulin the patient can be fed, but as the rest obtained by regulated fasting is not confined to the structures directly concerned in carbohydrate metabolism and has a beneficial influence in other directions, maybe helping to eliminate the cause of the disease, the full diet possible from the commencement of treatment with insulin is not always a real advantage to the patient.

In suitable cases, and used intelligently in conjunction with careful dieting and other forms of treatment, there can be no doubt that insulin is invaluable in diabetes mellitus. This is clearly evident in my own statistics, for in a series (Table I) of 250 unselected cases of which I have complete records during three years immediately preceding the discovery of insulin there were 66 deaths (26 per cent), while in the same number of cases treated in three years after the introduction of insulin there were

TABLE I

	Pre insulin Period			Insulin Period		
	Cases	Deaths	Percent deaths	Cases	Deaths	Percent deaths
Defective utilization (achimatic)	115	56	49	97	20	21
Defective storage (anapothetic)	117	10	9	138	6	4
Lowered threshold (epithymic)	18	0	0	15	0	0
Total	250	66	26	250	26	10

only 26 deaths (10 per cent). The improvement was accounted for mainly by a complete disappearance of pneumonia, influenza, and post-operative fatalities as causes of death, and by a reduction in the number of deaths attributed to coma from 19 to 6 during the insulin period.

For purposes of comparison and treatment cases of glucosuria may be divided into three main groups, irrespective of any theory as to the cause of diabetes, by relatively simple tests: (1) Those where there is defective utilization and defective storage of sugar, or, briefly, the "achimatic" variety ( $\alpha$ =absence of,  $\chi\mu\epsilon\alpha$ =nose), characterized by a high blood sugar and a low lactic acid content of the blood in a fasting condition. (2) Those where there is difficulty in storage but no obvious defect of utilization, the "anapothetic" variety ( $\alpha$ =absence of,  $\alpha\pi\theta\eta\kappa\eta$ =storehouse), in which the fasting blood sugar and lactic acid are normal, although hyperglycaemia develops on feeding. (3) Those where the utilization and storage of sugar are normally carried out and the sugar content of the blood is not high, even after a test meal of glucose, but glucosuria occurs on feeding, from unusual permeability of the kidneys for sugar, which may be termed the "epithymic" variety ( $\epsilon\pi\iota$ =upon,  $\theta\upsilon\mu\alpha$ =door). It is instructive to see how the introduction of insulin has affected the death rate of each group. As might be expected, achimatic glucosuria was a much more fatal condition than the anapothetic variety in pre-insulin days, the death rate in my cases working out at 49 per cent in the one group and 9 per cent in the other. After insulin became available the percentage of deaths in the achimatic group fell to 21, and in the anapothetic group to 4, so that, although insulin effected a noteworthy saving of life in both, the relative mortality remained practically unchanged.

It is true that all my patients since 1923 have not been treated with insulin, for I have always maintained that the inconveniences necessarily attending its use are not compensated by the advantage gained, except where a suitable diet is not otherwise obtainable, and I think my results support this view. The twofold power possessed by insulin of promoting the storage and the utilization of sugar should render it particularly useful in cases of achimatic glucosuria, where both functions are at fault, and I found it necessary to prescribe it in 64 out of 97 (66 per cent) of the cases of that type coming under my care in the period under

TABLE II—Insulin Period

	Diet			Insulin		
	Cases	Deaths	Percent deaths	Cases	Deaths	Percent deaths
Defective utilization (achimatic)	33	6	18	64	14	22
Defective storage (anapothetic)	131	6	5	7	0	0
Lowered threshold (epithymic)	15	0	0	0	0	0
Total	179	12	7	71	14	20

review (Table II). Of these 14 (22 per cent) have died, 2 of coma, which developed shortly after the injections were discontinued contrary to my advice, 2 apparently from the effects of insulin, but in the remaining 10 deaths

\* One of the papers read in opening a discussion on insulin therapy in diabetes mellitus at the Annual Meeting of the British Medical Association, Edinburgh, 1927.

occurred from causes not directly connected with defective carbohydrate metabolism such as cancer, tuberculosis, and nephritis. There were 6 deaths in the 33 cases of diabetic glycosuria not treated with insulin (18 per cent). 3 were due to coma occurring in patients who refused the injections and the other 3 resulted from cancer, nephritis, and old age respectively, causes which could not have been prevented by insulin.

In my experience patient suffering from glycosuria arising from defective storage rarely need insulin and I have found it necessary in only 8 out of 138 cases (6 per cent). Seven of these improved rapidly and then condition has remained satisfactory, but one who refused the treatment died of coma. This patient accounts for one of the 6 deaths in the anapothectic group not treated with insulin, where there was a total death rate of 5 per cent, all the other patients died from causes not susceptible to the influence of insulin (Table III).

TABLE III—Causes of Death Insulin Period

	Achiatric		Anapothectic		Total
	Died	Inulin	Died	Inulin	
Accident	0	1	0	0	1
Age	1	0	2	0	3
Carbuncle	0	1	0	0	1
Graves disease	0	1	0	0	1
Inulin in	0	2	0	0	2
Malignant disease	1	2	2	0	5
Nephritis	1	1	0	0	2
Pancreatitis	0	3	0	0	3
Refined treatment	3	2	1	0	6
Tuberculosis	0	1	1	0	2
	6	1	6	0	2

Epithelial glycosuria is not a fatal condition, and since there is no defect of carbohydrate metabolism treatment with insulin is not called for in fact it is contraindicated as a disturbance in the balance between the internal secretions of the ductless glands which may cause serious or even fatal hypoglycaemia results.

The effects of insulin upon the activities of the ductless glands have not received the attention they deserve. The acute symptoms arising from a large overdose are well known but the results of chronic hyperinsulinism from therapeutic doses are, as yet, almost unrecognized although they are of considerable practical importance. The most common is polyuria due probably to the neutralizing effect of insulin upon the internal secretion of the pituitary. This may develop occasionally into a condition closely resembling diabetes insipidus. Conversely a partial chemical neutralization of the injected insulin by the pituitary secretion with a compensatory hyperactivity of the suprarenals, thyroid and parathyroids appears to explain to some extent the varying effect of the same dose on carbohydrate metabolism in different cases and in the same case at different times which is often so puzzling. Occasionally patients are met with in whom insulin has comparatively little effect on the hyperglycaemia unless very large doses are given and if these are continued hypoglycaemia suddenly develops probably owing to exhaustion of the pituitary and overstimulation of the suprarenals with consequent ischaemia. Two of my patients died from rapid heart failure probably brought about in this way, and in three others where death was attributed to "pancreatitis" the symptoms were of a similar character, but associated with acute abdominal pain. It is important to realize that, although injected insulin may be chemically as efficient as the internal secretion of the pancreas it is not physiologically equivalent and the larger the dose the greater is the difference between the artificial and the natural condition which results with consequently increasing risk of disturbances like those I have mentioned developing. In the keto diabetes of children and young adults there is

some justification for comparatively large doses of insulin being given, at least for some time if constant supervision is possible, but in chronic cases, and especially when the patient is over 25 or 30, they are not necessary, and, in my opinion entail needless risks. I usually aim at restricting the dose to an amount sufficient to protect the patient from ketosis and enable him to metabolize 60 or 70 grams of carbohydrate a day, irrespective of whether sugar is passed in the urine or not. This plan appears to work satisfactorily and I have cases where as much as 50 or 60 grams of sugar have been excreted daily for several years without any apparent ill effect. In some instances I give a preparation of insulin by the mouth, for, although this does not improve sugar utilization, I have experimental and clinical evidence that it may materially assist the storage of carbohydrate so that, alone in anapothectic glycosuria or in conjunction with small injections of insulin in the milder forms of diabetic glycosuria it is a useful method of treatment if its limitations are borne in mind. Dried preparations of pancreas containing the active digestive ferments given by the mouth are also useful in some cases particularly when analysis of the faeces shows that there is defective digestion owing to sclerotic changes in the gland, or when growth and development are delayed or have ceased in children.

The most spectacular results of insulin therapy are seen in connexion with the treatment of diabetic coma. The effect is often almost magical especially in young people but some elderly comatose diabetics respond very little to insulin injections, and then only temporarily. The blood analyses made in my cases have shown that as a rule, the failure of the treatment is actually more apparent than real for the hyperglycaemia and ketosis are controlled in the usual way if appropriate doses are given, but, owing to the presence in the circulation of accumulated toxic products of defective nitrogenous metabolism upon which insulin has no effect, the coma either persists apparently unchanged or is relieved only for a time, death ultimately occurring from uraemic or amino acid poisoning. It is therefore never wise to give too sanguine a prognosis as to the outcome of the insulin treatment unless it is certain that the coma is only a direct consequence of defective fat and carbohydrate metabolism and is not dependent upon, or complicated by the effects of serious renal and hepatic damage preventing the detoxication and elimination of nitrogenous waste products.

#### DISCUSSION

Dr R. D. LAWRENCE (London) agreed that the use of insulin in patients with uncomplicated diabetes could restore them to normal health and strength. In fact, it was impossible to recognize these patients as diabetics unless they were watched critically at meals or seen having injection treatment. Insulin might fail however to restore health in those who did not use it properly and in cases where other organic disease was undermining the health. In infections much larger doses than usual were necessary. Dr Lawrence had seen only one case which failed to respond to insulin and even then it kept the patient free from coma. He had lost several coma cases in spite of energetic insulin treatment and in all these the cause of death seemed to be an intensely depressed circulation. When the patient was pulseless or nearly so insulin could not be expected to act. The speaker had found it impossible to keep severe cases sugar free continuously with only two doses of insulin a day, but rarely thought it necessary or wise to give more since the patients did equally well on two doses and led a more comfortable existence. The only contraindication to insulin in severe diabetes was angina or cardiovascular degeneration. Here insulin should be given with great care and no chance of hypoglycaemia should ever be risked, as the latter was apt to precipitate an attack of angina. Dr Lawrence had tried most of the mouth preparations advertised as being useful in diabetes and had found them quite useless. He did not agree that senile diabetes was different from the juvenile type, and thought that Professor Maclean had produced no evidence that the difference was one of kind and not merely of degree. Moreover, the evidence on which Professor Maclean had based his condemnation of alkalis

in the treatment of coma did not seem sound. The speaker thought that small doses of sodium bicarbonate must tend to restore the diminished alkali reserve to its physiological normal and that any rate could do no harm. He pointed out the advantage of "double strength" insulin in the case of patients who required large doses of insulin, because most practitioners were unaware of its existence. His experience with synthalin led him to believe it was of no practical value in its present form. It might be gathered from Professor Maclean's paper that there was no need to weigh the food in diabetes, whereas Dr. Lawrence considered this essential until the patient could gauge the correct quantity of food without actual weighing.

Dr. O. F. F. LEECH (London) said that insulin did not always succeed in uncomplicated diabetes mellitus, and gave details of a few cases which had failed to react. He suggested that it was possible that the glucagon of von Noorden was absent in these cases, and that this might account for the apparent improvement referred to by Dr. Crummond following the administration of pancreas by the mouth. He did not agree that synthalin proved too toxic in all cases. Occasionally when a man's occupation made hypoglycemic attacks probable if he took insulin, then synthalin might prove useful, he had seen more than one case in which this had happened. He had circularized his patients who had been on insulin, and 325 had replied, of these, insulin had been increased in 27 per cent, remained unchanged in 35 per cent, diminished in 26 per cent, and was no longer needed in 2 per cent. The diet had not remained constant, it had been increased in 33 per cent, remained the same in 62 per cent, and been diminished in 5 per cent. Some 6 per cent of his patients had died, this was probably too low a figure, since it was difficult to trace those who did not reply. Incidental infections accounted for many patients who had to increase the insulin. Time recovery occurred most frequently among patients who were treated shortly after the onset of the disease. He did not wish to be dogmatic, but would like to record the view that if patients with early acute diabetes were well fed and given enough insulin to keep the sugar in their blood below 0.15 per cent all the time, there was a chance of true recovery.

Professor D. M. LEE (Edinburgh), as the result of examining his records, had found that of some 760 patients treated by him only about 300 had required insulin. Dieting alone had sufficed for the treatment of the remainder. There could be no doubt that careful regulation of the food intake still remained the most important factor in the treatment of diabetes. The indications for the employment of insulin were the presence of clinical acidosis or of acetonaemia threatening coma, severe emaciation, a too low limit of tolerance, and failure to respond to simple dietary restriction. When the patient was first seen the decision must be taken whether he could be safely treated by dieting only, which must be carefully and conscientiously carried out by the patient. Weighing and measuring the food substances were essential at first, but later any intelligent patient could estimate the correct values at sight. The urine must be kept sugar-free at all times, and the patient's weight be maintained at a satisfactory level. Although a continuous absence of sugar was no guarantee that the blood sugar values were normal, practical experience had proved that this method of control was adequate. Experience had shown that patients taking insulin did best when the weight was not allowed to exceed the average for age and height.

Diabetes, when properly treated, was not a continuously progressive condition. Definite improvement commonly occurred, and most cases after careful treatment were able to reduce the amount of insulin or had considerably to their dietary. Many showed a variability in pancreatic activity, the reason for which was not always obvious. Insulin therapy probably promoted complete arrest of the disease in many instances. It was not the case that once a patient had taken insulin it was dangerous to discontinue it. Some 33 patients in Professor Murray Lyon's series, after courses of insulin lasting from two to eight months, had been able to give up its use for a time. In 10 of these

the improvement had only been temporary, sugar returning for some cause such as toxæmia or careless dieting. The degree of recovery in some of the subjects had been so striking as to suggest that certain cases of diabetes were curable, the most striking examples had occurred in young adolescents where the condition had been of short duration. A few of the other subjects were admittedly borderline cases where the maximum insulin employed had been only 10 or 15 units, but seven patients had at one time required over 40 units daily. In one remarkable case a young woman for a long period received as much as 170 units a day, then improvement followed fairly rapidly, and eventually she was able to do without the drug altogether, she had not had any for fifteen months. This type of result suggested that the pancreas could not have been badly damaged, but that something was neutralizing both the patient's and the injected insulin. In cases where the disease advanced this was not uniformly continuous, but moved in definite stages, punctuated by intercurrent attacks of coma or infection, or by a period of dietary indiscretion. In Professor Murray Lyon's series only some ten cases belonged to this type, and it was very important to realize that the disease was not necessarily continuously progressive. Factors in the return of glycosuria included suspension of treatment or the use of a new batch of insulin weaker than usual, for some time past, however, the standardization seemed to have been entirely satisfactory and uniform. Other causes were improper feeding, "nervous" or emotional states, conditions characterized by toxæmia, such as tonsillitis, respiratory catarrhs, influenza, and various forms of sepsis, and lack of exercise. Some of these causes of glycosuria were easily recognized, and if discovered in time did little damage. The most harmful appeared to be the toxic conditions. The occurrence of an attack of coma often appeared to be followed by a reduction of tolerance. In the speaker's series of cases 47 patients had died, 7 apparently from cancer, and 5 from apoplexy, 3 were otherwise accounted for, and in 5 cases the cause of death had not been ascertained. This left 27 deaths due to diabetes, and in 10 of these the dieting was known to have been unsatisfactory. Death was preceded in the majority of the cases by coma, which was brought on by pneumonia in 5 instances, by various infections in 11, and by alimentary upset in 5. Most of these deaths did not occur in hospital. The patients who did were not necessarily the most severely diabetic, and their deaths could not have been predicted before the onset of the fatal illness.

Professor L. BLUM (Strasbourg) said that there were two indications for the use of insulin: (1) the absolute or vital, as in coma, severe acidosis, infectious disease, or surgical intervention with anaesthesia, and (2) the relative—the temporary use for a short time only in milder cases in order to give them new strength, or to cure complications such as furunculosis, eczema, pruritus, or neuritis. It was generally necessary to continue the insulin until the end of life in severe cases, or when coma had occurred. He had had three cases, however, where the coma was produced by intercurrent disease such as influenza and angina, in which it was possible to stop the insulin after a few weeks. The great danger for diabetic patients under chronic insulin treatment was infection, and particularly tuberculosis, it was essential to examine the lungs from time to time not only by the usual physical methods but by x-rays. In the treatment of coma three things were necessary: (1) Sufficient doses of insulin (40 to 50 units for an injection) given intravenously every half-hour under careful and permanent supervision. In order to avoid hypoglycæmia it was necessary to watch the patient carefully during the injections, if unconscious patients showed signs of reaction (opening the eyes), or conscious patients experienced any special sensations, then the insulin had already produced an effect. Glycosuria was a sure sign that more insulin was necessary, if the urine was sugar-free there was danger of hypoglycæmia if more insulin was given. As a general rule when the patient was under clinical observation glucose was not given. (2) Large quantities of food. This organ often contained a great quantity of retained food, after large the blood pressure might rise.

(3) Medium doses of sodium bicarbonate (20 to 30 grams), to restore the sodium content of the organs and fluids, which was greatly diminished in coma. Professor Blum thought that the cardiac failure in the form of coma which he had called the cardio-vascular form of coma was partly due to the low alkali content of the organs. The use of insulin was particularly difficult in some cases of diabetes where a low hyperglycaemia (0.15 to 0.24 per cent) co-existed with a severe acidosis, and where diabetes was complicated by nephritis with hypertension. In these latter cases the urine was sugar free but the blood sugar was high. He had treated over 2,000 patients with insulin but had never seen a case resistant to insulin. By increasing the dose he had always been able to reduce the hyperglycaemia though very large doses were sometimes needed.

Dr C GRAHAM (London) thought that the mortality tables referred to by Professors Maclean and Petren were rather astonishing. The tables for England and Wales showed that there had been a steady increase since 1900 and even before that year. In 1917 a big decrease occurred which was almost entirely in the deaths of persons over the age of 50. This period was coincident with the severe rationing of the war and continued until 1919. From then until 1923 the increase reappeared but since the introduction of insulin there had been a slight decrease in the males and an increase in the females. This result was rather perplexing until the figures were examined in decades. The decrease showed that a decrease took place in both males and females until the age of 50 after this age there was a slight decrease in the males but an increase in the females. The speaker's analysis also showed how few people died of diabetes in the early decades compared with the large number who died after 50. The decrease in the figures for the young people was quite satisfactory when the varying conditions of treatment were considered and it was remembered that insulin was still a new form of treatment. He disagreed with Professor Maclean in the distinction drawn between true diabetes and the glycosuria as seen in elderly people. The speaker believed that there was no essential difference between the condition of the elderly person with a high blood sugar and glycosuria and the young adult. The elderly person had a low sugar tolerance and the condition grew worse very slowly, but after five, ten or fifteen years if the patient had not died of something else meanwhile the condition might be indistinguishable from that of a young adult. The primary action of insulin was to enable the sugar to be stored in the muscles and this was the defect which was first seen in the patient with mild diabetes. The belief that the condition was not a true diabetes was partly responsible for poor and inefficient treatment. This was most regrettable, since the elderly person was very liable to suffer from the effects of boils, carbuncles and gangrene of the leg. The eye complications (retinitis and cataract) were also more liable to progress if the diabetes was untreated whereas with insulin the condition seemed to be arrested. This type of patient responded very well to treatment either by diet alone or with the assistance of insulin. A carbohydrate tolerance of 50 to 70 grams might be regained and the patient be able to give up insulin, since the condition had a tendency to improve instead of slowly getting worse. Dr Graham believed that if patients older than 50 were treated more carefully the mortality figures would show a definite fall instead of an increase. He disagreed with Professor Maclean about the harm which alkali could do to a comatose patient and added that Professor Blum had shown that the tissues of the comatose patient contain very little sodium. The experiments of Dr Goldblitt to which Professor Maclean had referred were made on a healthy man with a normal alkali reserve and the large dose of alkali would produce an alkalosis. This alkalosis was the probable cause of the persistence of the keto after the alkali had been given. The comatose patient had a low alkali reserve and the dose of alkali was usually insufficient to do more than make the alkali reserve normal. For these reasons the speaker did not think that reasonable doses of alkali could do any harm but nowadays they were rarely necessary since insulin acted so well. Professor Petren had said that the adminis-

tration of dextrose to the comatose patient did harm. If there were facilities for estimating the blood sugar it was unnecessary to give any dextrose, but if the blood sugar could not be estimated it was a wise precaution to start the active treatment with a dose of two ounces of dextrose together with 70 units of insulin.

Dr C G LAMIE (Edinburgh) said that there were many causes of glycosuria, while insulin was a specific remedy for pancreatic diabetes its value in other conditions had not been firmly established. Some controversy had ranged around the question as to the essential difference if any, between pancreatic diabetes in young persons and the common glycosuria of elderly individuals. Certain differences between the two types could be noted as regards their response to insulin. Thus many of the cases of glycosuria in elderly persons were remarkably resistant to insulin a given dose producing a relatively small decrease in the output of sugar. Moreover sudden withdrawal of even large doses of insulin might be followed by little if any acidosis whereas in pure pancreatic diabetes the development of severe acidosis under the same conditions was the rule. Administration of glucose to such patients caused the respiratory quotient to rise to levels which indicated that carbohydrate was being utilized. Further improvement in tolerance in patients under treatment took place slowly over a long period. It seemed possible that the underlying cause of the peculiar features presented by these cases was an interference with the diffusion of glucose from the blood plasma into the tissue cells without necessarily much interference with the utilization of glucose once it got into the cells. This was suggested by the fact that the renal threshold was often remarkably high owing to the impermeability of the kidneys for glucose and by the appearance of symptoms of hypoglycaemia with blood sugar concentrations sometime much above the normal level. In such cases it was impossible to keep the blood sugar at a normal level a relatively high concentration of sugar in the blood being necessary to bring about sufficient diffusion into the cells. The permeability of the kidneys to glucose gave a rough measure of the permeability of cells in other tissues and in treatment it was sufficient to abolish the glycosuria and to find the dose of insulin which would be just less than sufficient to produce symptoms. Some recent experimental work by Loewi, Hausler, and Dietrich seemed to have an important bearing upon the point at issue. These workers found that hyperglycaemia, however produced—whether by glucose administration, pancreatectomy or administration of adrenaline—caused the appearance in the blood of a dialysable substance to which they had given the rather unfortunate name of *glycogenin*. This substance, when injected into rabbits, caused hyperglycaemia, and its addition to a suspension of red blood corpuscles *in vitro* inhibited the diffusion of glucose into them from the surrounding medium. If it were to be supposed that in certain individuals there was an excessive production or defective elimination of such a substance it would seem possible to interpret many of the facts and to reconcile the conflicting views which had been expressed.

Dr T B SMITH (Hirogato) agreed with Dr Lawrence that there was a definite group of patients in whom it was impossible to restore food tolerance even with insulin, in such cases several other possibilities must be considered—namely, sepsis, disease of the thyroid or pituitary gland, malignant disease and mental instability. He wished to draw particular attention to this last factor as the association of mental instability with diabetes was more frequent and of greater importance than was recognized. In one of his patients in whom anxiety neurosis was latent acute diabetes occurred apparently as the result of financial worry. It was satisfactorily controlled with insulin and dieting. Three years later while constantly balanced without glycosuria the patient became acutely and fatally manic. In another case markedly "temperamental" it had so far been impossible even with insulin to obtain any improvement either in tolerance for food or in the general condition. Apparently such patients possessed some substance capable of neutralizing insulin.

## PULMONARY ASBESTOSIS.

BY

W E COOKE, M.D., M.R.C.P.,  
Director of the Pathological Department, Wigan Infirmary  
(With Special Plate)

In the BRITISH MEDICAL JOURNAL of July 26th, 1924 (p 147), I published a short note on the woman who is the subject of this paper. The only similar case on record was that of a man admitted to the Charing Cross Hospital in 1899, who died in 1900. Dr E L Middleton of the Home Office kindly lent the notes of the case, and of the evidence given before the Departmental Committee on Industrial Diseases in 1906 by the late Dr H Montagu Murray, under whose care the man had been. This patient, a man aged 33 years, had worked in the carding room of an asbestos factory for ten years prior to his admission to hospital. He informed Dr Murray that he was the sole survivor of ten men who started work with him in the carding room, the others had died, presumably as the result of their occupation. A post-mortem examination was held and the diagnosis of pulmonary fibrosis was confirmed. Dr Murray in his evidence refers to "splenoid lung sections which show 'splenoid' are the salient facts of the first and, down to 1924, the only record of a death due to asbestos.

That these two cases stand alone is very surprising. The asbestos industry is more than 2,000 years old, and we know that asbestos factories, up to quite recent years, have been devoid of any appliances for the prevention and extraction of dust. The remark of Dr Murray's patient is suggestive, and medical men have long suspected asbestos dust to be the cause of lung conditions in workers in badly ventilated factories.

Asbestos is a physical paradox—a mineralogical vegetable, both fibrous and crystalline, elastic, and brittle, is capable of being carded, spun, and woven as wool, flax, or silk. A single strand can be spun to weigh less than an ounce to 100 yards, and a cloth manufactured which weighs less than 8 ounces to the square yard. It occurs in every country, but is never found in any two countries alike, nor, indeed, in any two parts of the same country.

## Historical

Asbestos is apparently indestructible, and its fire-resisting qualities were known to the ancients. The Romans mined it from the Italian Alps and the Ural Mountains. Herodotus (circa 450 B.C.) described a cretation cloth made from asbestos. Pliny (circa A.D. 50) mentions the difficulty in weaving it. Strabo (circa 30 B.C.) and Plutarch (circa A.D. 70) both speak of the wicks of the lamps of the Vestal Virgins being made from asbestos, so called because they maintained a perpetual flame without being consumed. Pausanias (circa A.D. 175) refers to a gold lamp made by Callimachus of Athens for Minerva, the wick of which was made of Cyprian linen, "the only linen which is not consumed by fire." Later (A.D. 1250) Marco Polo writes that he had seen Tibetans using cloth that withstood fire which was made of a "Celestial Mineral of Earth found in a Mountain."

Although its valuable properties have been known for thousands of years the modern adaptation of asbestos to the industrial arts dates from only a few years ago.

## Composition

Asbestos is one of the silicates, and its varieties are numerous. Wherever it occurs it is found associated with

other minerals, more especially with chromite and magnetite. The composition of the well known Italian and Canadian fibres is as follows:

	Italian Fibre	Canadian Chrysotile
Silica	40.30	40.87
Magnesia	43.37	41.50
Ferrous oxide	0.87	2.81
Alumina	2.27	0.90
Water	13.72	13.55

The purest asbestos, having fibres of extraordinary length, occurs in Northern Italy. Asbestos may contain from 0.5 to 15 per cent of iron oxide, but asbestos yarn is prepared from mineral as free as possible from iron. To get rid of the difficultly soluble iron, asbestos is soaked in orthophosphoric acid solution and washed in water before manufacture. The percentage of iron, then, is of recognized importance.

## Manufacturing Process

The process of manufacture resembles that of cotton. The crude mineral is subject to mechanical treatment in a grinding machine. The heavier rock is separated by gravity, and the remaining asbestos passed through carding, roving, and spinning machines, and from these to the weaving sheds.

During the carding process, and to a less extent in all the processes, a very considerable amount of dust is generated. In up-to-date factories all machines are fitted with extractor covers and the dust removed. In the first factory where the patient the subject of this paper was employed no method of dust removal was used, and the atmospheric conditions were occasionally so bad that workers in her particular room could not see each other.

## Asbestos Fibre and Dust

Microscopically asbestos fibre is seen to consist of two very different elements. The bulk of the fibre is translucent and glistening, with here and there black opaque angular particles (Fig 1). Minute black granules also are present. These black particles are actually part of the fibre, but their appearance suggests a different chemical composition and different physical characters from the translucent portion. The dust generated during manufacture is seen to consist of these sharp angular particles and minute granules, suggesting, of course, that they are more brittle than the translucent part of the fibre. These particles are found in very small numbers in the finished article. Mr T H Byrom, F.I.C., analysed several samples of dust, and found that the dusts containing the greater numbers of these black particles contained the largest amount of iron. The iron content of the finished article, raw material, and dust is as follows:

Finished article	Iron (as ferrous oxide)	0.1%
Crude raw material	Iron (as ferrous oxide)	2.61%
Dust from carding room	Iron (as ferrous oxide)	18.4%

From these results it appears conclusive that the blackened brittle parts of the asbestos fibre are the iron-containing portions—the bugar of the manufacturer, the cause of "dust," and a danger to the health of workers in the process of manufacture.

## Clinical History of the Case

The deceased, a woman aged 33 years, commenced work at the age of 13 years in an asbestos factory in which no provision was made for the extraction of dust. From an early age, soon after commencing work, she suffered from a cough, which did not interfere with her general health until 1917. She was then 23 years of age, and had been working thirteen years. From that time until 5 years later (1922) her attendances at work were intermittent owing to ill health. She missed occasional days and one or two periods of some weeks, until she finally ceased work in July, 1922.

Up to this she complained of cough, dyspnoea, expectoration

PULMONARY ASBESTOSIS  
 (Illustrating the papers by Drs. H. E. Coon and Stewart McDonald)

and inside. The physical signs in her chest were those of fibrosis of the right lung. In July 1922 signs of cavitation were noted the sputum became more profuse with sweats and irregular temperature and he died on March 14th 1924.

An x-ray plate showed extensive fibrosis, more marked in the right lung, two calcareous glands at the root of the left lung and two small calcareous particles in the base of the left lower lobe.

#### Microscopical Appearances

*Left Lung.*—The pleura is thickened over the entire surface of the lung and shows the remains of dense adhesion to the chest wall and pericardium. The lung is hard and small. The glands at the root of the lung are large and on section are black, how a thickened capsule and some calcareous particles. On section the lung is seen to be fibrotic and to a large extent the lung tissue being replaced by fibrous tissue. Dense strands of fibrous tissue from the pleura intersect the lung. In the apex there is a large cavity the size of a peeled tangerine orange. The middle and lower lobes show numerous small areas—varying in size from a hazelnut to a pin's head—of calcification some of which have preceded to cavitation. The bronchi are dilated.

*Right Lung.*—The pleura is thickened and shows the remains of adhesions to the chest wall. The thickening and adhesions are not so marked as in the right lung. The lung is firmer than normal. At the root of the lung are two large calcareous masses, one the size of a large hazelnut the other about half that size—calci tuberculous glands. The other glands are black and show pyridinosis. In the left apex there is an area of old scar tissue about the size of a Spanish piece and a cavity the size of a walnut. Scattered throughout the lung are small areas of denser calcification than the rest of the lung, some of which show definite calcareous particles, others small areas of calcification. There is a considerable increase in the fibrous tissue.

Three outstanding features are presented by sections from this case. The first is the enormous amount of fine granular pigment in the peribronchial fibrous tissue, walls of alveoli and in phagocytes scattered through the sections. The particles of this dust are similar in size and shape to the black granules seen in the asbestos fibre.

The second unusual feature is the presence of large old angular particles (Fig. 2). These are situated in areas of fibrosis and in cascading areas. They vary in size from 5 to 500 microns in length. The particles are so large—masses of them are seen in certain areas—that they must have occluded small bronchi. Fibrosis of the alveoli supplied has taken place and later necrosis as seen in Fig. 3.

We have never seen anything parallel to this in pneumoconiosis due to other dusts, nor have we been able to find such occurrence in literature. On comparing these lung particles with asbestos dust there is a striking resemblance in size, shape, and colour. In fact it is very easy to take each single particle found in the lung sections and immediately find its brother in a slide made from the dust.

We cannot think there is any reasonable doubt that the particles in the lungs are the heavy, brittle iron-containing fragments of asbestos fibre. The more extensive involvement of the right lung is thus explained. The heavy particles would pass more easily down the more vertical right bronchus than the horizontal left bronchus.

## HISTOLOGY OF PULMONARY ASBESTOSIS

BY

STUART McDONALD M.D. F.R.C.P.  
Professor of Pathology University of Durham  
(With Special Plate)

My remarks are confined to the histological appearances in the lungs in this condition with special reference to certain foreign bodies of most unusual appearance which are present both in the alveoli and interstitial substance of the lungs. The observations are based almost entirely on material supplied from the case described by Dr. Cooke. The investigation has been conducted in the pathological department of the University of Durham College of Medicine.

I may state, however, that the appearances are practically identical with those observed in a second case of this condition, sections of which I have had an opportunity of examining through the courtesy of Dr. F. M. D. Cleave of Armley, Leeds.

#### Histology

Numerous sections have been made from both lungs. The changes are more marked on the right side, but the

appearance in the two lungs only differ in degree. They may be summarized as follows:

1. There is well marked diffuse emphysema with chronic bronchitis and some emphysema.

2. There is well marked anthracosis.

3. There is an extensive tuberculous condition with chronic phthisis.

4. In the alveoli, bronchi, and bronchioles and also in the interstitial fibrotic areas are certain foreign bodies which will be described in detail later (Fig. 7).

As the communication deals specially with the nature of the foreign bodies, the general histological features will be dealt with very briefly.

The interstitial fibrosis is such as might be expected as a result of a combination of a pneumoconiotic condition and a chronic tuberculous infection. The typical whorled formations seen in a more purely silicotic condition are not present. There is marked endothelitis in the smaller branches of the pulmonary arteries, some are thrombosed and organized. Many of the smaller bronchi are obliterated, some have still a cross-looking centre. Some of the alveoli show the usual metaplasia of the lining cells into cuboidal form. The fibroblasts and thickened wall of the bronchi in many places gradually merge into the areas of diffuse fibrous overgrowth. There are numerous foci of lymphocytic cells among the fibroblasts. Some of these seem obviously derived from lymphoid tissue in the bronchial wall. The interstitial fibrosis is progressive. The tuberculous condition is obvious histologically. Tubercle bacilli were not detected, but the histology is characteristic. The lesions are chronic in character and there is no special indication of any recent exacerbation. There is well marked chronic bronchitis with lymphatic spread and numerous fibrocytes deposits with giant cell systems (see Fig. 8). The bronchi which are not specially the seat of tuberculous change show extensive peribronchial thickening. There are numerous empty cisterns in the alveoli showing the majority of cases some thickening of their wall and containing certain cells apparently derived from the lining cells, a singular cisternal change is seen in the terminal bronchioles, some of which are dilated.

#### The Foreign Bodies

The large black and irregularly fragmented bodies which have been described by Dr. Cooke were not very obvious in the material I examined, but were clearly seen in some microscopical preparations on which I had the opportunity of examining. I shall not refer to them specially, but confine my attention to certain highly characteristic and much smaller bodies which are abundant in all the sections examined. Some of these are free but many are phagocytosed by the large mononuclear cells in the alveoli (Fig. 5). Some are easily included in comparatively small phagocytic cells, but the majority are large, varying in size from 20  $\mu$  to 70  $\mu$  or even more in the case of certain elongated forms. The smaller bodies are rounded and homogeneous and all have a distinct yellowish brown colour, except the blood pigment. The longer forms have a highly characteristic appearance, strongly suggestive of an organic structure. Most have an irregular appearance which on closer examination can be resolved into a closely set series of rounded discoid bodies (Figs. 4, 5, 10 and 11). In some cases the globular forms are arranged along the more filamentous forms and occasionally are clustered at the ends or the rods simulating sporangia of a hyphomycetes (Figs. 5, 6, 10 and 11). Some have club-like extremities at one or both ends of the filament. Others again suggest the appearance of minute crustacean forms (Fig. 10) but closer examination does not support the idea of either vegetable or animal origin. These bodies do not stain with the ordinary aniline stains but preserve their original yellowish-brown colour. They give a well sustained reaction. They give a characteristic prussian blue reaction with potassium ferrocyanide and dilute hydrochloric acid. The reaction is not so obvious unless the solutions are slightly warmed. Where the bodies are too large to be phagocytosed by individual cells they tend to become surrounded by plasma-membrane masses. Many of the phagocytes contain much carbon pigment in addition. Though these bodies are mainly found in the alveoli and

in fundibular passages, they are also present in the caecum and sigmoid flexures. One in particular (see Fig. 12) measured about 75  $\mu$ . It is clear and segmented in its middle part, but the extremities are nodular and clubbed. It is difficult to imagine that a foreign body of such length could be transported by phagocytes, but they may represent obliterated The bodies have been examined with the micro-spectroscope, but so far no clue as to their nature has been obtained by this means. They are not refractile by polarized light.

Nature of the Bodies

We have shown these preparations to several pathologists, but the appearances are new to them. To confirm our own opinion we have submitted them to experts in zoology, who are unanimous that they are not of animal nature. We have also submitted them to botanical and chemical authorities, and though there has been a considerable difference of opinion, some regarding them as hyphomycetes, the general opinion has been that they are not vegetable forms.

The fact that exactly similar bodies have been found in the lungs of another asbestos worker, and, so far as I can ascertain, have not been found elsewhere, would seem to indicate that they are essentially derived from or associated in some way with the asbestos itself. It is also certain that they do not in any way resemble conchoidal, largely composed of calcium and other salts, and also containing iron derived from blood, such as have been described as asbestos-like forms in the spleen, and which may closely simulate mycelial filaments. The hypothesis advanced is that these bodies are portions of asbestos fibres in the process of absorption and absorption by hydroids, either by direct chemical action or by enzymes. The particular variety of asbestos with which this patient worked was a Canadian serpentine (chrysotile). It would probably contain silica and a magnesium salt in about equal proportions (40 per cent) with up to 2 per cent of iron oxide, 1 per cent of aluminium, and water. From its high resistance to heat we are apt to regard asbestos as indestructible, but, given time, it is possible for hydroids of such silicates to occur, even in pure water. Such hydroids would be hastened and intensified by the presence of CO in the pulmonary alveoli, and the process. Even under these conditions the process would necessarily be a slow one. The magnesium could be separated out as relatively insoluble carbonate, or more soluble bicarbonate, which in turn would be converted into any other salt for which there happened to be the appropriate acid available.

The iron existing in a ferrous condition in the presence of an oxidizing agent might be converted into the ferric state, and subsequently precipitated as hydroxide. The silicate might pass into a colloidal state, at first in sol form (orthosilicic acid), later passing into a gel (metasilicic acid). If this were so in sol form, it would tend to remain associated with the surface of the asbestos fibre by adsorption, and might be held there until it became a gel. In time the gel might absorb the solution, and so gradual conversion of the fibre into a mass of gel would occur. There might be in the tissues sufficient aluminium material to offset rapid gelatinization of the sol, particularly if, as would be the case here, the sol was being slowly produced. The fact that the gel is of high surface tension, and formed at an irregular rate, would give it a spheroidal structure and account for some of the appearances seen here. Whether this be the exact explanation or no, it is at least a hypothesis which should be capable of experimental verification. As has been held by Gyo and others, in cases of silicosis there may be a direct chemical action of silica on the tissues apart from the purely mechanical irritation of the particles with the production of fibrosis. Orthosilicic acid, as has been shown in action, but rapid conversion into metasilicic acid would minimize its action. As to the relative part played by the asbestos and the

tuberculous infection in this case, in relation to the fibrotic change, it is difficult to say, but it is a reasonable assumption that the tuberculosis was a superadded infection, and sections examined a considerable degree of fibrosis without apparent tuberculosis. The immediate cause of death in that case was a terminal broncho-pneumonia. Till some experiments work is completed the exact nature of the foreign bodies must remain in doubt, but their highly characteristic appearance may well prove to be an important diagnostic point in the recognition of the lung of a worker in asbestos.

I am much indebted to Dr. Cooke for material from his case, sections, to P. L. Robinson, D.Sc., of the Chemical Department Armstrong College, for his advice and suggestions on the chemistry of the silicates, and to Professor W. H. Lang, F.R.S., of Manchester, for a reasoned opinion as to the non-bacterial nature of the foreign bodies.

Dr. W. E. Cooke has given a short account of the history of asbestos, also of the processes of its manufacture into cloth-like structures much in the same manner as raw cotton fibre is woven. He has told us that in the cradling department a considerable quantity of dust is evolved. The dust is usually done in the countries where the mineral is quarried. Canadian rock is crushed in Great Britain. Our workers are therefore less exposed to the harmful influence of the dust—a fortunate circumstance, since the rock frequently contains as much as from 50 to 60 per cent of more of silica.

With the exception of Dr. Cooke's paper on pulmonary asbestos published in 1924, and the details of a fatal case published by Dr. Montague Murray in the *Charing Cross Hospital Gazette* in 1900, there has not been, to my knowledge, anything written in this country upon this subject. I have had, however, the opportunity of visiting asbestos factories in America, and of seeing cases of pulmonary asbestosis through the kindness of Dr. Hildow and Dr. Greave of Armley, Leeds. It may, I think, be safely said that there must have been several deaths of workers in British factories from the malady, but as no autopsy and microscopic examinations of the lungs were made the deaths were probably certified as pulmonary tuberculosis.

Asbestos manufacture is largely a familial occupation. It has been carried on in this country only for a little over thirty years. Cradling and spinning of the fibre are important processes in the manufacture of asbestos goods. In these departments many women are employed, mothers being succeeded by their daughters. Where ventilation of the cradling and spinning rooms is properly attended to the atmosphere is fairly clear of dust and floating fibre, otherwise in these operations considerable quantities of dust become suspended in the atmosphere. In a British factory the dustiest process is "hand beating" of the finished mattresses used for covering and protecting the internal machinery of automobiles. This work should only be undertaken in a room separated from the main parts of the factory, with open windows at one end and strong down-draughts at the other, but even with this precaution men working therein should wear masks.

Recently, with Dr. Greave of Armley, I examined two women who are the subjects of pulmonary asbestosis, one aged 48 and the other 39. The older patient was one of the first to commence work thirty years ago in the particular factory I visited. At that date no danger from dust was anticipated so that no effective ventilation of the workshops was attempted, such as prevails today by several firms, and is extremely commended. She has worked a year ago on account of increasing physical

up work a year ago on account of increasing physical by several firms, and is extremely commended. She has worked a year ago on account of increasing physical

SIR THOMAS OLIVER, M.D., F.R.C.P.,

debility, shortness of breath and cough. At present she has no expectoration; her respiratory capacity is one inch. Although the apices of both lungs in front are resonant, there is distinct flattening of the percussion note at the bases. The respiratory murmur at the apices and mid-lungs is coarser than usual, and the expiratory murmur is prolonged. At the right base the respiratory murmur is feeble, and small dry friction sound is heard. Towards the base of the left lung and extending into the axilla are heard small moist rattle sounds suggestive of crepitation having taken place here also small friction sounds can be heard. Similar physical signs prevail posteriorly. The apex beat of the heart is displaced upwards and outwards; it is felt as well as the nipple; a circumstance which combined with marked accentuation of the second sound of the heart heard over the pulmonary artery, suggests that valvular changes have already occurred in this lung. Although the patient states that she has no expectoration, this was present six weeks ago and when examined was found to be free of tubercle bacilli. There is no enlargement of the external glands.

The other patient, aged 39, has been an asbestos worker for eighteen years. She had no illness until four years ago when she developed cough and attacks resembling bronchial asthma. After remaining away from the factory for three months she returned to her employment and followed the occupation for three years, when she married and as in the early months of her pregnancy she lost considerable weight she retired from the factory. Although reduced considerably in weight and the subject of cough all through her pregnancy, her infant daughter, who is 14 months old, is healthy and well developed.

The patient complains of a dragging in the chest without actual pain. There is noticeable shortness of breath on slight exertion, and she complains of morning cough with expectoration. The sputum has been examined and is negative as regards tubercle bacilli. Her appetite is poor. She weighs 8 st. a drop of 3 st. having occurred within the last two years. Her heart is healthy; the apex beat is not displaced but the second sound over the pulmonary artery is distinctly accentuated. The apices of her lungs are resonant. Here the respiratory murmur is coarser than usual and the expiratory is prolonged so that the inspiratory and expiratory murmurs approach each other in equality. Moist rales are heard in mid-axilla and small friction with crepitation is heard at the base. This woman's mother, who is aged 60, is still working in the factory.

From what I have seen clinically of pulmonary tuberculosis it resembles silicosis of the lungs in the marked shortness of breath on slight exertion, deficient respiratory capacity, physical debility, and, in examination of the sputum, not too far advanced cases, absence of tubercle bacilli, but since fibrotic changes are developing in both of the patients to whom I have alluded there is almost sure to develop in such cases what has not already taken place, pulmonary tuberculosis.

The clinical picture of pulmonary asbestosis differs slightly from that presented by a patient the subject of ordinary tuberculosis of the lungs, in so far as there is a pronounced deadening of the skin varying from mild bronzing to slight blueness, a degree of shortness of breath in excess of the physical signs, a greater amount of general disability, little expectoration, and comparative absence of night sweats.

## AN ACTIVE CONSTITUENT OF THE PREPARATION CALLED "GLUKHORMENT"

BY

H. H. DALE, C.B.E., M.D., F.R.C.P., Sec. R.S.,

AND

H. W. DUDLEY, O.B.E., M.Sc., Ph.D.

(From the Department of Biochemistry and Pharmacology, National Institute for Medical Research, Hampstead, London.)

In May of this year Professor von Noorden published in the *Klinische Wochenschrift* an account of a new pancreatic preparation which had a controlling effect on carbohydrate metabolism, but unlike insulin was effective when administered by the mouth. To this preparation the name "glukhorment" had been given and the title of the paper made it clear that the substance was regarded by the author as containing a new anti-glycosuric principle naturally performed in the body. On information, evidently supplied to him by the chemist responsible for devising 'glukhorment,' Professor von Noorden stated explicitly that in spite of indications in the patent specification which might suggest some connexion of the active principle with a guanidine derivative no such derivative and in particular no synthalin,\* had been added and further that the finished preparation contained no guanidine derivative or any kind in recognizable amount. Professor von Noorden drew the cautious conclusion that, if the activity were due to a guanidine derivative, it would have to be one of extremely high activity. In July of this year one of us (H. H. D.) received a communication from the Horment Company who were manufacturing glukhorment, stating that they were sending material in the hope that clinical trials of it could be arranged. In due course this and several subsequent consignments of glukhorment were sent by the Horment Company with a request for their trial.

A consideration of preliminary reports on the mode of action of this preparation on the human being and on laboratory animals suggested a strong similarity between its effects and those with which we had become familiar, through experiments then for some time in progress on the action of synthalin. Some of the glukhorment

was immediately placed in the hands of one physician, who will presumably report his experience with it in due course. The physiological resemblance to synthalin was pronounced, however, that before the question of wider clinical trials was considered it was thought desirable to make a simple chemical examination, in order to confirm the fact that the preparation was free from synthalin and similar guanidine derivatives as stated in the paper by Professor von Noorden, of which copies had been submitted by the Horment Company in support of their request. The result of this first test showed clearly that a guanidine derivative strongly resembling synthalin was present in substantial amount in the glukhorment tablets as submitted for trial. The evidence thus early obtained was a once so clear and so surprising that it was considered desirable to use a further quantity of the material submitted in order to obtain precise information as to the nature of the substance in question. The isolation of the substance was made easy by the fact that the nitrate of synthalin is a remarkably insoluble salt.

### Chemical Isolation of Glukhorment of a Guanidine Derivative closely resembling Synthalin

Two hundred glukhorment tablets were powdered, the powder weighing 60 grams was thrown into 1 litre of boiling water and the mixture was kept gently boiling for fifteen minutes. The liquid was then filtered, while still hot from a large mass of insoluble protein.

The filtrate was evaporated *in vacuo* with the addition of 95% alcohol to prevent frothing to a volume of 120 c.c.m. On standing it set to a jelly; this was warmed to 40° when it became fluid and concentrated in nitric acid was added until the reaction of the liquid was strongly acid to Congo red. A white crystalline nitrate separated from the solution on standing, and the liquid no longer set to a jelly when cold. The crystalline material was collected by centrifuging, washed in the centrifuge with a small quantity of dilute nitric acid and dissolved in about 25 c.c.m. of hot water. This solution was boiled with charcoal and filtered. To the hot filtrate 0.5 c.c.m. of 6 per cent nitric acid was added, and the nitrate crystallized on cooling. This was filtered off and dried, it weighed 1.135 grams. It was then converted into the picrate by dissolving it in water and adding a saturated solution of sodium picrate until no further precipitate was produced. The picrate was filtered

\* Synthalin is the synthetic compound decamethylenediguanidine introduced by Franz Volkmann and Wagner as an antidiabetic remedy for oral administration and already the subject of numerous reports.

AN ACTIVE CONSTITUENT OF "GLUKHORMENT"

Rabbit (1) developed convulsions after six hours and rabbit (2) after four hours. When in convulsions they were killed, and samples of their livers taken for glycogen determinations.

Rabbit (1) had 0.05 per cent liver glycogen  
Rabbit (2) had 0.02 per cent liver glycogen

These results are closely similar to many which have been obtained in this laboratory by similar injections of synthrin into rabbits.

The glycogen contents establish beyond question the fact that synthrin is either synthrin itself, or a substance so closely related to synthrin as to be indistinguishable from it, by the chemical and physiological tests applied. The information on which Professor von Noorden had based his publication was clearly incorrect. Substantially more than 1 per cent of a guanidine derivative, indistinguishable from synthrin, was easily extracted from the tibias, and it was quite certain that the pieces would not yield, in pure form for weighing, more than a part of what was originally present. The point obviously had a practical interest, and no decision of the results of our investigation, and to place Noorden of the details of our experiments.

Professor von Noorden's reply, dated November 17th, 1927, made it clear that he had already received some-what similar information from another quarter, and that he had taken the first opportunity of making a public statement concerning the position which he had decided to assume. He informs us that this same part of his lecture on November 8th in the Berliner Fortbildungskurs fur Agero will be published in No. 23 of this year's volume of the *Zeitschrift fur praktische Fortbildung*, about December 1st.

(Extract from a lecture delivered on November 8th, 1927, by Professor C. von Noorden.)

Concerning synthrin for insulin I will only report briefly, since nothing of a final nature can be said concerning them. The insulin like nature of the guanidine derivative synthrin is not contested by anyone, provided that sufficient doses are given, but the dividing line is often indistinct, scarcely recognizable, and shows wide differences in individuals. From late The communications become constantly synthrin accumulations in comparison become constantly synthrin accumulations and stronger in comparison become constantly synthrin accumulations. The position of synthrin to day.

Concerning glukhorment you will wish to hear something more definite. I reported on it at the end of May, since already one month earlier, before the conclusion of the preliminary experiments, a communication concerning it had reached the daily press, through a deplorable indiscretion. The favorable conclusions which I then published in the *Klinische Wochenschrift* (No. 22) are based on uncontested facts. The preparations which I received at that time, and on which I remained dependent until the beginning of the scale, and, according to the assurance on word of honor, which I then demanded and received, were prepared by strong, which digestion of fresh pancreas substance for about eight days, without any kind of addition. To which part of the fermentation mixture, rich in peptides, the undoubted antihypocous action was attached, remained uncertain. I left the question open at that time, as to whether the powerful (typical) digestion a very potent active guanidine derivative might have been produced.

As happens also in other departments of chemistry, the preparations obtained by the later development of manufacture on a large scale failed by far to attain the activity of the not others. When, after a long absence I again took up the investigation a few weeks ago, I received for the first time preparations from the large scale manufacture which, indeed, were inferior in activity to the original ones, but were nevertheless usable. Now Weichowski has raised a few days ago in the Medical Union of Prague, that he found a guanidine derivative in glukhorment, which corresponds with synthrin in important reactions and in its pharmacological properties.

We are indebted to Mr. H. P. Marks for investigating the action of this substance on two rabbits (each weighing 2 kg.) fasted for twenty-four hours, then into (1) 20 mg. and into (2) 50 mg. of the substance, in aqueous solution, were injected subcutaneously.

Physiological Tests of the Substance Isolated from Glukhorment

The chloraurates were analysed and found to contain the same percentage of gold, which, moreover, is precisely dichloraurate—namely, 42.1 per cent.

H<sub>2</sub>O of crystallization 0.2146 gram, dried at 102°, gave 0.0901 gram Au = 42.0 per cent  
Chloraurate (from glukhorment) Contained no H<sub>2</sub>O of crystallization, 0.2125 gram, dried at 102°, gave 0.0894 gram Au = 42.1 per cent.

It will be seen from this fairly thorough chemical comparison that the substance isolated from glukhorment is indistinguishable, by the tests applied, from synthrin as prepared by Kahbaum. It must be either identical with synthrin, or so closely related to it that an elaborate analytical investigation with large amounts of material would be required to distinguish between them. A sample from a batch of glukhorment submitted quite recently, with the suggestion that this would prove to be better than earlier batches, contains the same synthrin-like substance in about the same proportion.

As to whether it is a case of true identity or not Wiechowski obtained no definite evidence according to his letter to me. Assuming identity, scientific logic would present only two possibilities.

Either in spite of assurance to the contrary without my knowledge and against my will the guanine preparation known as synthalin is added to glukhormont. In that case, we should be dealing with at least a gross breach of trust in relation to myself and to the public. According to the assurance repeated to me a few days ago on the word of honour of the responsible chemist, at no time either earlier or recently has synthalin been mixed with glukhormont.

Or the remarkable fact would be presented that from the pancreas together with other products of decomposition a substance chemically and pharmacologically at least very similar to synthalin can be obtained—a fact which would be of great importance for the study of intermediary metabolism. I recall in this connexion that I indicated in advance as a possibility, the formation together with numerous other decomposition products of a guanidine derivative of great activity exceeding that of synthalin.

You will see that I speak quite openly. Given the identity of the two active chemical substances present in synthalin tablets and in glukhormont tablets the decision between these two possibilities must not be a matter of impression. These are questions for experimental investigation of which, on my part also, there shall be no lack.

We need add but little to Professor von Noorden's frank statement. This publication of our own findings is made at his explicit request, and may be regarded as a contribution to the experimental investigation which he himself indicates is imperative. The details of the work done in Professor Wiechowski's laboratory have appeared since we communicated with Professor von Noorden and learned from him of this other investigation of glukhormont.<sup>2</sup> Dr Lungeker's evidence of the chemical identity or close chemical similarity with synthalin is much less convincing

than that which we have been able to obtain. The physiological comparisons made in Prague are, on the other hand, more thorough than those which we thought it necessary to make. The conclusions are practically the same as our own.

Our evidence, of course, provides no means of discriminating between the two possibilities which Professor von Noorden mentions. If a substance, so different in structure as synthalin from any hitherto known to occur in the body, were produced by tryptic digestion of pancreatic tissue, the fact would obviously have an interest far beyond that of the immediate question concerning the nature of the active constituents of glukhormont. The point of practical importance and the one which impels upon us the necessity of publication, is that glukhormont cannot be regarded as free from synthalin, or similar guanine derivatives. On the contrary it contains either synthalin or a substance so closely allied as to be indistinguishable without prolonged investigation and it contains this substance in sufficient quantity to play an important part in whatever therapeutic or other actions the preparation may possess.

It should perhaps be added that we are not in a position here to discuss the therapeutic value of glukhormont as such, or the possibility that the action of a substance like synthalin might be modified by the presence of the known constituents of a pancreatic digest. Our concern is to ensure that the physician in charge of a patient who has shown intolerance to synthalin should not be led to administer glukhormont by the mistaken supposition that it contains no synthalin or similar substance.

## MEDICAL, SURGICAL, OBSTETRICAL

## GALL-STONE FORMATION

The following is rather an unusual case and worth reporting.

An unmarried woman aged 30 a cook was operated on in hospital in 1924 for gall stones. The stones were removed and the bladder was drained. During the last year she had recurrent attacks of colic. In September 1927 I was called and found her in a definite attack of colic. When this had subsided I operated and removed the gall bladder. On opening it after the operation I found two stones inside, which had formed round the purse-string suture inserted at the first operation, the suture running through the whole length of the stone.

E. A. THORNTON

E. WILSON HALL, F.R.C.S. Ed.

## PREGNANCY COMPLICATED BY MITRAL STENOSIS

The following details of a case of pregnancy associated with mitral stenosis and terminating fatally appear to be worthy of record.

A woman aged 26 who had had a normal pregnancy and labour eighteen months previously was admitted to hospital six and a half months pregnant with malaise which had lasted for some weeks. She had had rheumatic fever as a child and on admission was found to have mitral stenosis without any signs of failure of compensation. The temperature, pulse and respirations were raised; there was some abdominal tenderness especially over the gall bladder region in the left iliac fossa and in both renal angles. The spleen was doubtfully palpable; the urine negative. On the following day her condition was obviously worse; slight albuminuria had appeared and there was oedema of the

feet and back; the renal tenderness was less and repeated examination of the lungs revealed nothing pathological. On two occasions she had syncope attacks and nearly died three days after admission; therefore labour was induced by means of a prostatic catheter, no anaesthetic being employed. Delivery followed normally within six hours; a live and healthy foetus was born but died a few hours later owing to prematurity. During the twenty-four hours following delivery the patient's condition was very much better apart from an irritating cough which prevented sleep until heroin was given when she had a good night. On the following morning the temperature had dropped to 98°; the patient felt better and complained only of slight nausea. At midday she had haematemesis, quickly followed by the passage of a quantity of blood from the rectum two hours later. She died. At the necropsy all organs showed chronic venous congestion; there were large vegetations on the heart valves especially the mitral but no signs of emboli anywhere. At the junction of the middle and lower third of the oesophagus a small ruptured vein was found without evidence of varicosity. About one inch of clot was drawn out from the vein and was found to be a *plastic* clot and not thrombus.

I am indebted to Dr Statham and Dr Herapath for permission to publish this case.

Resident Obstetric Officer, Bristol Air Force

## AN EARLY CYSTOSCOPIC SIGN OF RENAL TUBERCULOSIS

The following is a sign occasionally seen with a cystoscope before the bladder picture becomes typical.

The sign may be described as a rebound of the coloured urine on the pathological side (methylene blue or indigo-carmin being used). The accompanying diagram explains it. The rebound is caused by the stream impinging on the lower edge of the ureter opening which is slightly raised, hardened, and thickened.

**RADIOLOGICAL PITFALLS**

At the Royal Society of Medicine on November 17th a combined meeting took place of the Sections of Electro-therapeutics, Medicine, Surgery, and Orthopaedics for a discussion on radiological pitfalls.

Sir Henry Gairdner, President of the first-named Section, who was in the chair, said that Murray's English Dictionary defined a pitfall as "a trap or snare." He was sure that all radiologists or those who had to do with x-ray results had it times fallen into pitfalls, and he hoped the discussion might show how these were to be avoided.

Dr. J. E. Barclay (Manchester), opening for the Section of Psychological Diseases, insisted, in the first place, that the radiologist's function was, not to make a diagnosis, but to force a link in a chain which resulted in a diagnosis. He regarded a pitfall as nothing more than an appearance which gave rise to a blunder, self-evident as soon as the interpretation was known. To make mistakes on the way to knowledge was more honourable than to escape them by thinking the quest. It was necessary to settle down quietly to study the radiogram. Routine might cause apparently routine be carried out, it would obviate many errors. If the radiologist knew the clinical diagnosis in advance he

[illegible]

Dr. E. I. Sprague said he considered that the first and greatest pitfall was that of allowing radiological to involve other special examinations to take the place of a study of the early history and clinical symptoms of disease. The radiologist, the surgeon, and the physician must know something of the history and the physical examination of the patient before they can make a correct diagnosis. The radiologist should not be called in until after a careful physical examination has been made. The radiologist should not be called in until after a careful physical examination has been made. The radiologist should not be called in until after a careful physical examination has been made.

Mr. Mr. Fox (Section of Surgery) devoted his attention especially to mistakes in the diagnosis of fractures with clinicians who said that the radiologist was allowed to take too important a part in the diagnosis. That was especially true when it was a matter of teaching. Radiology having come to stay, however, one had to appreciate that it was a physical method which could be used as an addition to the employment of the senses, but by no means as a substitute for them. The value of stereoscopic pictures was shown by him because two views had not been taken, he strongly urged the value of stereoscopic pictures. He showed a number of slides of fractures of crura of tibia and the sesamoid bones, such as at the so termed minimum joint and the sesamoid bones, illustrating the diagnosis of loose cithige in the joint. Usually, radiology is not too indicative whether a bone is common or unusual and that is a pity.

Dr. Arthur F. Hurst referred to ten radiological pictures in connection with gastro-intestinal disease. He said this is a finding in any of peristalsis as the wave passed along the greater or lesser curvature, and this the radiogram did not show. One should be careful about diagnosing a gastric ulcer near the cardia, most lesions in that situation were not ulcers at all, but congenital gastric diverticula. One should never diagnose pyloric obstruction from the pictures alone, even at that stage when struts, unless there are also exaggerated peristalsis, 85 per cent of cases of pyloric obstruction not due to the growth wave in the stomach—ulcer, "adhesions in the right ilio-foecal" area, "functional dyspepsia" or the persistence of undigested food in the appendix, but it should not be made, even when the appendix is as wide as the stomach, carrying out the most important test of inflicting the intestinal obstruction. In this condition, one should expect the terminal ileum to be dilated, and the pictures should not be so dilated as the stomach. The same could be said about the transverse colon. He at one time resorted to a series of pictures in a patient with a hypotonia, but he was not convinced that the tone of such a stomach was not normal rather than the usual. When one detected the existence of a pyloric obstruction, it was almost impossible to know what it was, because on giving a barium meal or an enema it disappeared and one saw the obstruction. It could be concluded that it was really a gastric ulcer, which was not so uncommon as some supposed.

Dr. A. C. Joravsky showed a number of slides illustrative of pitfalls in the diagnosis of intestinal conditions.

Dr. H. Wanner (Harrowgate) spoke on radiological pitfalls in reference to the teeth. He thought it would be generally admitted that no radiogram of the teeth would show a peristalsis, if not of the waves as depicted in the picture, the tooth, if taken out and cultured, might still prove to be infected. Some people held the view that a tooth which was still vital could not

be infected but that was a fallacy. Because a person's teeth were very bad it did not follow that his systemic disease was being produced by them.

Dr F. HENNINGSON JOHN spoke of cases in which became a lump in the abdomen is not evident to the rays after in cinema it is concluded to be due to a collection of faeces, whereas it might be in early phase of carcinoma which was hanging about a functional paralysis leading to fecal accumulation. In a case of recent apparently involving a patient for it was very important to radiograph the whole spine. He quoted a very instructive case in this connection.

### PYURIA IN CHILDREN

A joint meeting of the Sections for the Study of Disease in Children Therapeutics and Pharmacology and Urology was held at the Royal Society of Medicine on November 23rd. Mr. George I. WATSON, President of the Children's Section, was in the chair. The subject under consideration was the treatment of pyuria in children.

Dr L. A. COCKAYNE, in opening the discussion, said that his objects were twofold: first to show the necessity for making certain that cases resistant to treatment were really cases of simple pyelitis and not infections gifted on to some primary disease or malformation; and secondly to point out the necessity for ascertaining what proportion of a long series of cases of pyelitis were curable by hexamine or alkalis. Only in this way could some rough standard be found by means of which the newer remedies could be compared with the older ones and with each other. He emphasized the necessity for using all available means—radiography, cystoscopy, pyelography—in order to make a correct diagnosis. He dealt chiefly with pyelitis as this was the most common cause of pyuria in children. A culture specimen was necessary to verify the diagnosis as pus in urine in quantities sufficient to simulate that seen in pyelitis might be derived from a vulva which was not the seat of any obvious purulent infection. A differential diagnosis had to be made between calculus, streptococcal infection, haemorrhagic nephritis, and lesions of the central nervous system—for example, spina bina, puerile tabes dorsalis, and general paralysis of the insane or myelitis. Malformations of the urinary tract had to be considered as possible causes—for example, congenital phimosis, hypospadias, epispadias, ectopia vesicae, diverticula of the bladder, iliacant renal arteries, congenital stenosis or dilatation of the ureter. Many of these conditions might cause a pyuria usually due to *B. coli communis* that could not be distinguished from simple chronic pyelitis without the exercise of great care. No case of chronic infection of the urinary tract should be regarded as a pyelitis unless the possibility of mistaken diagnosis had been eliminated by means of radiography, cystoscopy, and pyelography. In all cases of long continued pyuria an estimation of the urea and non-protein nitrogen in the blood was of value. Nitrogen retention indicated damage to the kidneys. In his experience a very small proportion of cases of pyelitis in which there was no underlying cause failed to recover. In regard to the etiology of pyelitis whether of the newborn, of infants, or of older children, the great majority showed *B. coli communis* to be the infecting agent.

Passing to treatment, Dr Cockayne emphasized the primary necessity of flushing the urinary passages. This could be achieved in infants by giving plenty of plain or sweetened water between feeds. As much as one to two pints in the twenty-four hours could be given. It was impossible to give fluid by the mouth because of vomiting, then it could be given by the rectum with glucose and sodium bicarbonate or subcutaneously or intraperitoneally. Sufficient potassium citrate and sodium bicarbonate should be given to keep the urine alkaline, specimens of which should be tested at frequent intervals. If such cases were secondary to a gastro-enteritis which was still active, purgation, colonic lavage, and other measures should be undertaken in addition. In older children the symptoms were very variable, some had frequency of micturition and enuresis, or haematuria; others had constitutional symptoms such as recurrent pyrexia, con-

vulsions, or rigors. Sometimes the discovery of pyuria was only made in the course of a routine examination of the urine. The treatment of these cases consisted in rest in bed, milk diet, and a large fluid intake. For febrile cases either all time treatment or urinary antiseptics could be used. For febrile cases hexamine, 5 grains three to four times a day, was found to give the best results. Treatment should be continued a week after sterile urine had been obtained and a cure should not be pronounced until a further sterile specimen had been obtained one week after the treatment ceased. For resistant cases alternate weekly course of alkalis and hexamine seemed to give better results. The possibility of other infections such as typhoid, paratyphoid, bacillary dysentery, *B. pyocyaneus*, *B. proteus*, streptococcus, and staphylococcus should be borne in mind. Dr Cockayne added that his experience of the newer remedies—methanamine and hexylresorcinol—was too small to be of any value.

Dr ELIZABETH H. LEPPER then read a paper on the reaction of the urine in relation to the treatment of coliform infections with alkalis and with hexamine. This paper was the result of joint investigations by Dr Dorothy HIRE, Dr Marjorie Maitland, and herself. Dr Lepper stated that although it was a matter of general observation that the administration of alkalis in coliform infections of the urinary tract relieved the symptoms and apparently cured the patient, the reason for this was not clear. They had found that alkalis had no lethal effect on bacteria. The urine showed a slight increase in the number of bacteria present. A disappearance of the infection was a result of all alkali medication had never been seen by them. A second possibility was that the symptoms were relieved by neutralization of an acidosis. The blood was therefore examined in six acute cases before alkaline treatment was started. The bicarbonate content of the plasma in every case fell within normal limits. Thus there was no evidence of acidosis, and yet all these cases responded quickly to alkalis and the symptoms disappeared. They then considered whether the reaction of the urine was the factor determining the alleviation of symptoms. The pH of morning and evening specimens was estimated, and it was found that as soon as the urine became really alkaline—that is when the pH had reached 7.4 to 7.6—the symptoms were relieved. Early morning specimens were most acid unless alkalis were given at four hourly intervals throughout the twenty-four hours. It was thought that possibly the benefit from alkalinizing the urine depended on the local effect of the reaction of the urine on the inflamed tissues of the urinary tract. There was some evidence that alkaline fluids were less irritating to inflamed surfaces than acid ones. The hydrogen ion concentration might be of importance in determining the rate and force of the muscular contractions by which urine was propelled from the pelvis of the kidney to the bladder. The work done hitherto on this hypothesis had given contradictory results. The dose of an alkali could only be adequately controlled by testing the reaction of the urine with certain precautions. Mr. Lending's data were inevitable when the ordinary hospital routine of testing urine in an open jar with litmus was followed. Litmus was not a good indicator. Red litmus turned blue at pH 0.6—an acid reaction—a point at which symptoms were not relieved. A specimen in an open vessel quickly lost CO<sub>2</sub> and therefore urine if neutral when passed became alkaline after standing. The method proposed by Sir Charles Martin was to collect the urine in wide-necked stoppered bottles under toluene. The toluene prevented loss of CO<sub>2</sub> when the bottle was opened and also inhibited bacterial growth which would alter the hydrogen ion concentration. In summing up, Dr Lepper said that the administration of alkalis in coliform infections of the urinary tract cured the symptoms. Alkalis had no lethal effect on the bacteria nor did they act by neutralizing an acidosis. They altered the hydrogen-ion concentration of the urine and two ways had been suggested in which this might be of importance as regards symptoms.

Dr Lepper then passed to a consideration of the action of hexamine. If properly administered it was effective in combating coliform infections. Its action depended on its dissociation into formaldehyde and ammonia. In cases of coliform infection in adults 15 of hexamine was given

three times a day. The more acid the urine the greater was the amount of formaldehyde liberated. There was no formation of formaldehyde until the pH of the urine was less than 6.0. Results of adding acid phosphato in cases in which the pH was not so low as 6.0 were irregular. The greatest concentration of formaldehyde in the urine was 1 in 20,000. Experiments with various cultures of *B. coli* showed that a dilution of 1 in 20,000 allowed only a few bacilli to grow, whereas 1 in 10,000 was lethal. Some strains were more susceptible than others. Experiments were tried adding varying amounts of N/10 HCl to 1 per cent hexamine solutions. Hexamine and HCl made an excellent buffer mixture between pH 6.0 and 4.0. Hexamine therefore behaved like a weak base, probably forming salts with the hydrochloric acid. There was no considerable liberation of formaldehyde until pH had fallen to 4.0. The liberation of formaldehyde was increased at body temperature. The conclusions reached, therefore, were that there were two factors of importance in the action of hexamine as a urinary antiseptic: first, the capacity of the patient to secrete in acid urine, and second, the susceptibility of the infecting organism to the action of formaldehyde.

Mr. JOHN EVERIDGE next briefly discussed cases of pyuria which had not cleared up with alkalis or hexamine. He had concluded that in these cases there was an underlying organic cause, either in the gastro-intestinal or urinary tracts. He dealt with the surgical treatment of such conditions, and showed some interesting slides. Those who took part in the general discussion seemed to be in agreement that, except for Dr. Lepper's recent research work, all the remarks could have been endorsed twenty years ago, and that very little real progress had occurred in the knowledge of this particular subject. Dr. H. C. CAMERON emphasized the fact that cases of pyuria were often found in the course of a routine examination of the urine, and another speaker stated that he had proved in his own experience that 60 per cent of cases in children cured themselves.

The Chairman summed up by stating that what was needed was team work. A team of four—physician, biochemist, pathologist, and surgeon—should coordinate their findings on every case. Until this was done the study of pyuria in children could not greatly advance.

### THE SCIENTIFIC BASIS OF MEDICAL HYDROLOGY

The President of the Section of Balneology of the Royal Society of Medicine, Dr. L. C. E. CAMERON of Haringate, gave his presidential address on November 23rd, and made it a plea for further investigation with regard to the scientific basis of medical hydrology. Notwithstanding the recognition of balneology twenty years ago as one of the subjects which might fittingly be made the province of a special section in the newly formed Royal Society of Medicine, there were still many members of the medical profession who were quite ignorant of the science of medical hydrology or were frankly sceptical as to its results. The root causes of such scepticism, said Dr. Cuthrop, were both immediate and remote. Until quite recently there was practically no teaching or demonstration of the subject in any British school, and even now this country was far behind France, Germany, Italy, and the United States in this respect. Again, with all due acknowledgements to previous writers, there was still great need for a first-class British textbook of medical hydrology, one which would give not only the theoretical and scientific aspects of the subject, but also a clear account of how to administer the various treatments. A further cause of scepticism arose out of the fact that, although baths had been employed ever since Hippocrates, the practice had been purely empirical, and still remained so to a very large extent. The usual means and methods of applying water treatment which were available to the old practitioners were very simple: immersion baths, shower baths, steam vapour and hot air, mud baths, shampooing and massage, and water-drinking. Whatever observations were made by the old physicians were based on these simple means of hydrological treatment. It was not until the middle of the seventeenth century that any

attempt was made at a scientific observation of the physiological facts. He cited the work of Sir John Floyer of Lichfield (1649-1734), who was a pioneer of water therapy; in his experiments were to be seen the beginnings of research into the action of cold water in the treatment of disease. The earliest account of any attempt to make accurate analyses of English waters was by Dr. Thomas Garnett (1766-1802), who published an analysis of the Haringate waters. Among foreign workers he mentioned Winternitz, who, at the university clinic at Vienna, made memorable experiments into the physiological and therapeutic action of waters. Coming to quite recent times, Dr. Cuthrop cited some of the outstanding investigations in balneology during the last few years, such as the effect of various forms of baths upon blood pressure, and the influence of intestinal lavage upon toxic conditions of the bowel. In many such investigations the members of the Section whom he was addressing had taken a prominent share. Many questions yet awaited an answer, especially as to the limitations of thermal and mineral waters.

### TREATMENT OF SKIN DISEASES

At a meeting of the Aberdeen Medico-Chirurgical Society, on October 26th, Dr. J. F. CHRISTIE delivered his presidential address on skin diseases, with special reference to treatment.

Dr. Christie first emphasized the importance of accurate diagnosis, which in dermatology could only be taught clinically. He attributed the general lack of interest taken by the medical profession in skin diseases partly to the nomenclature and to the facts that affections of the skin were considered trifling or something to be ashamed of, and that proficiency in their treatment necessitated many years of study of large numbers of cases. Rest was as important therapeutically in skin diseases as in other affections of the body. Other primary considerations were the dressing of the case, the proper application of ointments, and the careful removal of adherent dressings. Soap and water should usually be avoided. Diet required careful regulation, including the cutting out of all spicy and highly seasoned foods in the acute stages of skin affections. In acute vulgaris general tonic medication must be supplemented by very thorough local treatment, sulphur in one form or other had been found to be the best, and Dr. Christie recommended the treatment described by McKenna with 'lotio albi,' which was applied by dabbing on to the face with a pledget of lint, three or four times a day until the skin began to crack and peel. After ten days equal parts of glycerine and stibic acid ointment were applied at night, and immediately given relief to the drawn skin. The lotion was still applied twice during the day and the mitigating ointment used nightly. In Dr. Christie's opinion the best time for beginning the mitigating ointment was ten days after the commencement of the lotion treatment, and he added that it was remarkable how a coarse, greasy skin, studded with blackheads, cleared up. X-rays were mentioned as giving perhaps the best results, but accurate electrical measurement and fractional dosage were considered essential. Dealing with ultra-violet light, the speaker was of opinion that most benefit was derived from this form of treatment in the acute lesions of acne. Colloidal manganese was not recommended, apart from its great value in cases of true boils. For scabies nothing had yet, in the speaker's experience, superseded the employment of sulphur ointment. In alopecia areata ultra-violet rays had given excellent results. Patients suffering from chilblains were divided into two types: the fat type, preferably treated with thyroid extract and Lugol's solution, and the thin type, whose the best results were obtained by giving calcium in some form, mention was also made of Crumpton Low's modified Bier's congestion method. Good results had been obtained in cases of nevus by using radium "slowly," and Dr. Christie thought that a cure might be effected in cases of nevus flammeus. In the treatment of acromioclavicular recommended plaster zinc oxide with 3 per cent of eucalypti, with this he has had under 1 per cent of failure. The interesting dermatitis artefacta was next dealt with, and many of the numerous pitfalls explained. For treatment of impetigo contagiosa, although the per-

area, the causes of muscular atrophy in cortical affections, the causes of spasmodic contraction in paralysis, the localization of the motor centres and of the several species of sensibility. Other chapters are devoted to epilepsy, disturbances of speech, frontal, occipital, and cerebellar lesions, and epileptic and subjective disturbances. Thirty-two cases of head injury and their symptoms are described, and the discussions of which they form the basis give a valuable summary of present views on the problems involved.

### COURT ETIQUETTE AS A CAUSE OF MADNESS

In *Le Mal Héréditaire* (second series) the indefatigable Dr CABANES continues his pathological history of the kings of Spain. In the first chapter he describes the last years of Charles II, the miserable sufferer from scrofula and fever with whom the line of the Emperor Charles V ended in 1700. The crown then passed to the grandson of Louis XIV of France, the Duc d'Anjou, who ascended the throne of Spain as Philip V. In his former volume Dr Cabanes described the eccentricities of Charles V's descendants Philip II, who used to put himself into a coffin which formed part of the furniture of his room, and who within a few hours of death placed his crown upon a skull, Philip III, who was asphyxiated by the fumes from his breeches because the only official entitled by etiquette to open the door of the king's chamber happened to be absent, Philip IV, whose life was carried on with clock-like regularity, with duly occupations that never varied throughout the year, and with a face, so it is alleged, that never changed its expression. It might have been thought, says Dr Cabanes, that the change of dynasty on the death of Charles II would have changed the conditions from which the kings of Spain suffered. But it was not so, and the Bourbons, like their predecessors, became the victims of their surroundings. Dr Cabanes contends that these surroundings were so sombre and sinister as to affect with the same neuropathic condition even the imported line of monarchs overshadowed by all-powerful first ministers, surrounded by spies, constantly controlled by their confessors or almoners royal, with no distractions except bull fights, autos-da-fé, and occasional hunting, it was not surprising that the sovereigns of Spain became first neuropaths, then psychopaths, and finally lunatics. Thus it was that Philip V became, after a time, as mad as Charles II, that Louis I was a morose and narrow devotee, that Ferdinand VI inherited the mildty of his father, and that Charles IV, who devoted loving care to a vast collection of watches and clocks, was a ludicrous monarch, completely under the thumb of his minister Godoy, and married to a queen who was another Messalina. Charles III alone gave any sign of being a normal individual. Dr Cabanes attributes this disastrous history, of more than two centuries' duration, to the etiquette which crushed all freedom and life out of its royal victims, and made the court for them a living tomb.

### NOTES ON BOOKS

SIR SAMUEL HOARE Secretary of State for Air, has written a vivid account of his flight in the Imperial Airways passenger aeroplane from England to India. His book, *India by Air*,<sup>1</sup> is full of excellent photographs and interesting stories of his experiences, and Lady Maud Hoare, in a short and very introduction tells us her sensations in rough weather. She was, she says, 'too interested to be frightened, was more comfortable than in a first class railway carriage, and spent much of her time in the air in writing. There is a thrilling account of an attempt to fly through a terrific sandstorm near Karachi. "In a few minutes the sand blotted out from view the land below. I could not see the faces of the pilot and the navigator. By further cups the altimeter began to fall from the 2,000 feet although the 200 feet mark, and from the 200 to the 20. We the pilot saw the sea, that at one time was not more than so to a yellow sea—a nasty grey sea with ugly white horses—do was in impenetrable wall of fog." The successful old pilot's simple

termination of a flight such as this shows the great progress made in the safety of travel in the air, and suggests that convalescent patients could be comfortably and quickly transported to Egypt and urgent cases requiring treatment could be brought to a suitable centre, as regular passenger services are now running.

*The Elements of Pharmacology*,<sup>2</sup> by Professor W. A. OSBORNE, is a little textbook written for the use of the medical students of the University of Melbourne. The author has aimed at setting forth the main facts of pharmacology in a concise form, and in this aim he has certainly succeeded, for the subject has been compressed into sixty-five pages. Such drastic compression of pharmacology at the hands of a physiologist will naturally raise mixed feelings in the breasts of the teachers of the former subject. Professor Osborne has, however, made a very good summary of the salient facts, and has also managed to produce a readable account of the subject. By discussing only a limited number of drugs, and by omitting such subjects as materia medica, dosage, and pharmaceutical chemistry he has avoided condensing the material into a mere catalogue. The book is evidently intended as an introduction to pharmacology for students who have not commenced clinical work, and should answer this purpose very satisfactorily provided that the condensed information it supplies is supplemented by lectures and demonstrations.

Last year (December 4th, p. 1072) we published a rather elaborate review of the *Medical Art Calendar* issued by Mr J. Philip Kinsman of the Hague. He has now produced a calendar for 1928, it contains a series of illustrations, some taken from pictures and some from books, all very well reproduced. This number has a good many illustrations of dentists and of surgeons at work, but there is one of a 'pothee' sitting in a room teaching his apprentice how to pound drugs, and another of a female writer doctor, pictures of female quacks are said to be uncommon. The *Calendar*, which is meant to be hung upon a wall, can be obtained from Mr Kinsman, S. Gravenhage, Noordinde 91, Holland, price 6s. post free.

### PREPARATIONS AND APPLIANCES

#### SYNTHALIN

"SYNTHALIN" (Kahlbaum) is a synthetic preparation recommended for use in the treatment of diabetes. It is given by the mouth. As many of our readers will be aware, this substance was produced by Frank more than a year ago, but has only just been released for general sale to the medical profession. Its constitution is given by Drs H. H. Dale and H. W. Dudley in a footnote to their paper, published at page 1027.

The vendors of the drug recommend it for 'cases of diabetes of slight and medium severity.' As a partial, or even complete, substitute for insulin in severe cases it seems generally agreed that its value is very doubtful.

The introduction of a substance which claims to be even a partial substitute for insulin, and to possess the two very important advantages that it is cheap, and can be administered by the mouth, is naturally a matter of considerable interest. Fortunately the Medical Research Council has been able to organize an investigation of the action of synthalin in several medical schools, and a preliminary report has been published (*Lancet*, 1927, ii, 517), this should be consulted by anyone intending to use the drug. The contributors to this preliminary report emphasize the fact that their experience is insufficient to permit of any final conclusion, but on the whole their reports are discouraging. Several investigators mention a disquieting number of toxic symptoms and, in particular, the drug is suspected of a direct toxic action on the liver.

Professor Maclean, in the paper with which he opened the discussion in the Section of Medicine at Edinburgh, on the results of insulin therapy in diabetes mellitus made a brief reference to the drug. As will be seen (p. 1019) he said that when given by the mouth it produced a definite effect in certain cases of diabetes, but added "The product, however, has marked toxic properties, and tends to produce gastrointestinal and other disturbances, so that its use in the treatment of diabetes is at present not practical."

Clinicians in this country admittedly have not yet had sufficient experience of the drug to permit of final judgement, but the evidence available suggests that it is one that must be used with great caution, and that, until our knowledge is more complete, it will be safest in the hands of those who have special experience of diabetes and who have special facilities for following the action of the drug.

FIG. 1. ELEVATION.

## EPSOM COLLEGE SANATORIUM

Plans have now been prepared by Messrs W. A. Pite Son and Lumley, architects, for a new sanatorium at Epsom College. It is proposed to erect a two-storied building of red brick with quoins and window dressings of red brick of a richer colour. Over the central portion there will be a sloping roof, but the remainder of the building will have flat roofs covered with asphalt. All the wards will face south, and ample provision is made for heating beds into the open air. Low pressure central heating by radiators will be used throughout the building, but the wards will have open fireplaces in addition. The boiler for the central heating and domestic hot-water supply will be placed in the basement below the kitchen wing, where also there will be a disinfectant for clothing and bedding. Food for the patients in the isolation and the non-infectious wards will be supplied from the main kitchen, a lift being used to the first floor wards. Cooling will be by gas. The building will be lit throughout by electric light. The floors of the wards will be covered with battens on a cement screed flush with a coved border and skirting in cement. The corridor floor will be of asphalt laid in a similar manner. Graded plaster with a final coat of sirapite or similar preparation will be used throughout.

The building has its long axis running east and west with a centrally placed main entrance on the north side opening into a hall to the right of which is the nurses' dining room and beyond the kitchen wing with servants' hall and quarters for a married couple who will act as cook and porter. To the left of the entrance hall will be a simply equipped operating room and beyond this the out-patient wing approached either from the corridor or by a separate outside entrance through which stretchers can be wheeled direct to the wards. Rooms for the medical officer and matron, waiting casualty, x-ray and massage rooms will be provided. At each end of the main corridor a sixteen-bed ward projects south, forming with a duty room, broom, sanitary annex and nurses' bedroom a complete unit. Separating these ward units and opening direct into the main corridor will be four single-bed wards and a dining and a recreation room, thus forming three sides of a square, the fourth or south side being open. The large sixteen-bed ward at the east end of the corridor will be an isolation ward. It will be shut off from the rest of the sanatorium by double doors and the only access to it by patients will be by means of a separate external door. All the other wards on the ground floor with a total of twenty beds are reserved for non-infectious cases.

The first floor is approached by two staircases, one of these opens out of the ground floor corridor at the west end and gives access to the staff bedrooms, the other leads from the lobby of the isolation ward to the first floor wards. It will consist of one eight-bed ward, one four-bed ward, two single-bed wards, and a small dining room

making with the sixteen beds on the ground floor a total of thirty beds for infectious cases.

We have received the following appeal for financial assistance for this undertaking, the cost of which is estimated at £25,600. The appeal is followed by the subscription list.

### APPEAL FOR SUPPORT

Sir—In your issue of December 18th 1926, you published a letter from the chairman of council of Epsom College appealing for financial help from the medical profession to enable the council to build a new sanatorium and isolation block which while providing adequate accommodation for the needs of the college would at the same time be a model for all other schools to copy. It was also pointed out that the present sanatorium built many years ago is uneconomical in working and its arrangements and accommodation in many ways do not conform to modern hospital requirements but could by a very moderate outlay be adapted as a school house for from forty to forty-five boys. The existing isolation block is a temporary work in building the licence for the use of which expires shortly making imperative the erection of a permanent building in the near future. Cases of scarlet fever and diphtheria are not dealt with in the isolation block but are sent direct to the isolation hospital of the local authority.

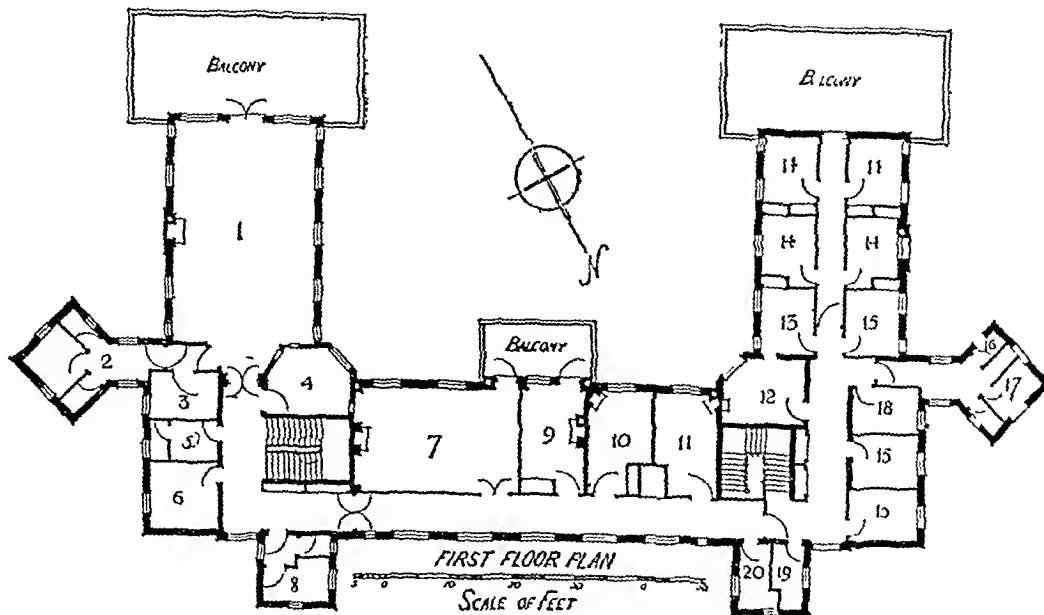

At Epsom following the practice of some other public schools no provision is made in the school houses for the treatment of cases of trivial illness but all cases however slight are treated in the sanatorium. This plan ensures every case being seen by a trained nurse at an early stage and by the medical officer who is promptly summoned whenever necessary but at the same time it also involves the provision of a large number of beds, thus is necessary in two schools which have sick rooms in the school house.

Experience shows that a well planned sanatorium with a properly apportioned number of large and small wards to accommodate 12 per cent of the boys in the school meets all reasonable requirements for both infectious and non-infectious cases provided that if a widespread epidemic of any particular disease occur one of the school houses is temporarily converted to hospital purposes.

By adopting the plan which has proved so successful and free from risk in the hands of Dr. Friend at Christ's Hospital of housing infectious and non-infectious cases under one roof but with separate means of access to each class of cases the architects Messrs William A. Pite Son and Lumley have at the request of the council designed a building which will be in every way a thoroughly up-to-date sanatorium convenient and economical to work and which it is estimated can be built for the moderate sum of £25,600.

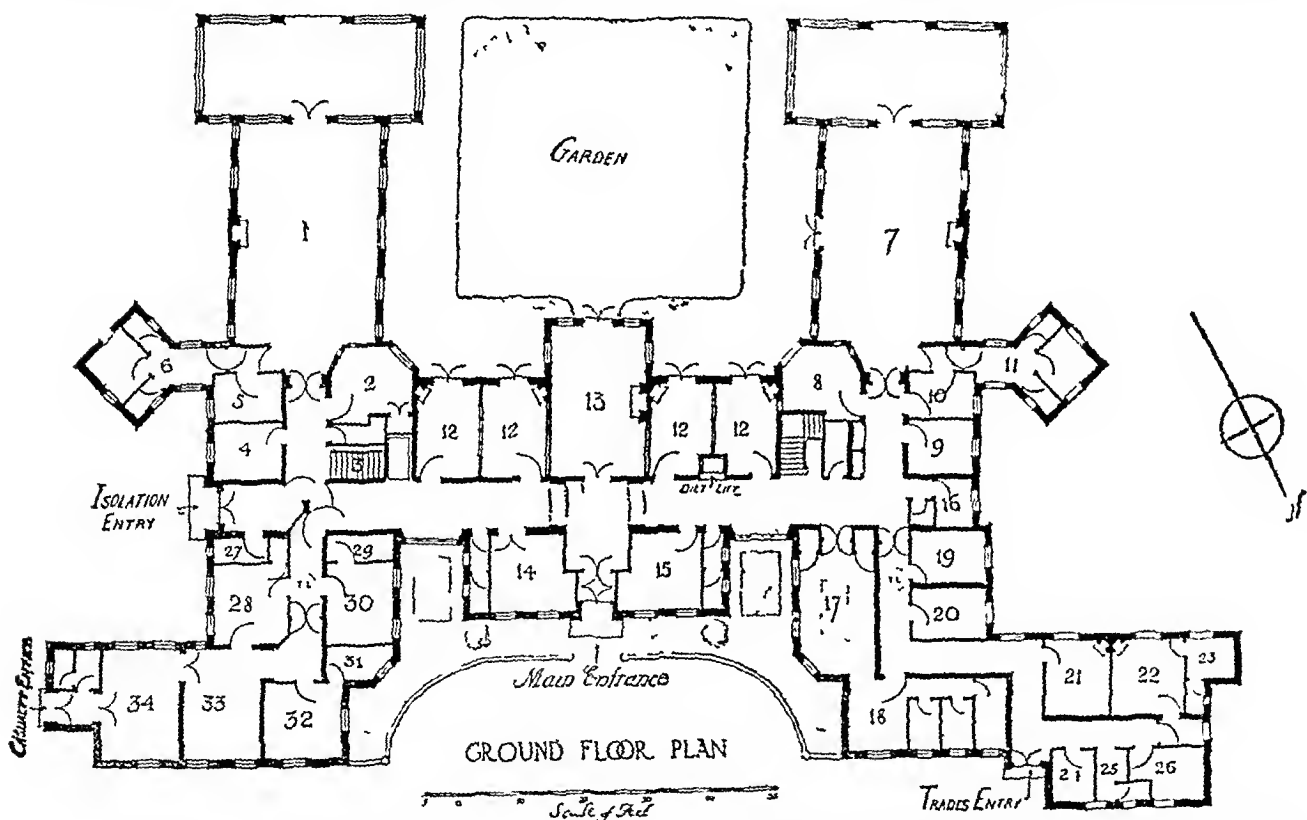

Taking 400 as the maximum number of boys in the school provision has been made for 20 beds for the non-infectious cases and 30 beds for infectious cases or 50 beds in all with ample accommodation for the nursing and domestic staff. The details of construction are shown on the plans and dealt with fully in the memorandum accompanying this letter so need not be further referred to here.

While the school fees paid cover the cost of the ordinary

Isolation Wing—1, Ward of 8 beds 2, Sanitary annexe (sink room, w.c., cleaner, lavatory, and soiled linen) 3, Bathroom 4, Duty room 5, Nurses' bathroom and w.c. 6, Nurses' room 7, Ward of 4 beds 8, Sink room (patients w.c. adjoining) 9, Single bed ward 10, Single bed ward 11, Dining room, with diet lift adjoining 12, Matron's

sitting room 13, Matron's bedroom 14, Nurses' bedrooms, 15, Domestic bedrooms, 16, Domestic w.c. and cleaner adjoining, 17, Nurses' bathroom and w.c. adjoining 18, Domestic's bathroom and lavatory 19, Box room 20, Bathroom for small wards

Isolation Wing—1, Isolation ward and solarium, 16 beds 2, Duty room 3, Staircase to first floor, isolation wing 4, Nurse 5, Bath room 6, Sanitary annexe (lavatory, sink room, w.c. and soiled linen) Sanatorium—7, Ward and solarium, 16 beds 8, Duty room 9, Nurse 10, Bath 11, Sanitary annexe (lavatory, sink room, w.c. and soiled linen) 12, Single bed wards 13, Dining and recreation room 14, Operation room, staff lavatory adjoining 15, Nurses' dining room, patients' lavatory adjoining 16, Bath for patients in single bed wards

(cleaner adjoining) 17, kitchen 18, Scullery with larders and store adjoining 19, Linen and mending room 20, Mattress store 21, Staff dining room 22, Married couple's room 23, Bathroom and w.c. adjoining 24, Soiled linen 25, Boots (w.c. adjoining) 26, Wood and coal store 27, Cleaner for isolation section 28, Medical officer 29, X-ray dark room 30, X-ray room 31, Dispensary 32, Matron's office 33, Casualty and dressing room 34, Waiting room with lavatory adjoining

#### Schedule of Staff Accommodation

Total number of beds	50

scholars, and the annual subscriptions and donations enable the Council to pay for the foundation scholars, an extraordinary expense, such as the provision of a new sanatorium, cannot be met without the aid of special contributions. It is for this reason that we venture to appeal to your readers to help the Council and make possible the provision of a sanatorium, built and equipped on the most modern lines, and worthy of a school in large proportion of whose scholars are the sons of medical men.

Donations received to date amount to £2,207 19s 6d, but until at least £15,000 is in hand it will not be possible to proceed with the actual erection of the buildings—land, etc.,

RAYMOND CHAWFURD,  
Chairman of Council of Epsom College  
WILLIAM HALL-WHITE,  
Treasurer  
ARNOLD LONDON,  
Chairman, Sanatorium Committee

## THE ROYAL SOCIETY.

### ANNIVERSARY MEETING

The anniversary meeting of the Royal Society of London was held, as usual, on St Andrew's Day (November 30th), when the Council presented its report for 1927, and the President, Sir ERNEST RHENIERS, gave an address.

#### THE REPORT OF COUNCIL

##### Research Appointments and Grants

Deep regret was expressed on the death of the first of the Royal Society research professors, Professor E. H. Starling. He was, the report recalls, appointed Foulerton Professor on April 1st, 1922, and carried on his research in a suite of laboratories in the Physiology Institute of University College, London, to whom the Society was indebted for this hospitality to its professor. "Professor Starling carried out a series of important investigations, especially on the mechanism of renal secretion, the results of which have appeared from time to time in the *Proceedings*, and his laboratories became a centre of attraction and of fruitful activity for a large number of younger physiologists from this and other countries. The Council have approved arrangements for the completion of the investigations on which Professor Starling was engaged by a group of these collaborators." The period of office for which Dr. H. W. C. Ymms was appointed Foulerton Student expired this year, and Dr. R. J. Ludford has been appointed to the vacancy for some years. Dr. Ludford has been engaged in part-time investigation in general, physiological, and pathological cytology, the award of the studentship will now enable him to devote his whole time to it.

Sums amounting to £5,617 had been allotted from the Government grants for scientific investigations, and £1,000 had been placed in the hands of the Council to meet urgent demands. Of this amount £320 had already been allotted.

#### Tropical Diseases

Researches into tropical diseases have been carried on by means of the Anonymous Bequest Fund under schemes recommended to the Council by the Tropical Diseases Committee. Notwithstanding the dangers and difficulties incident to the situation in North China, involving on some occasions serious personal risk to the Society's commissioner, Dr. Hindle, progress had been made with the investigation into kala-azar. A peculiarity of this disease in China appears to be the difficulty of infecting sand flies by feeding them on human cases. Dr. Hindle reported in November 1926, that the workers at the China Medical Board had failed to obtain flagellates in phlebotomus fed on human cases, but that he and his co-workers had had two positive results out of a considerable series of experiments. These observations are in marked contrast with those obtained with *P. argentipes* fed on cases of Indian kala-azar, but, reporting in February of this year on the results of experiments on the development of Chinese leishmania, the Royal Society's Commission concludes that there is strong presumptive evidence in support of the view that *P. major*, or *chinensis*, is concerned in the transmission

of the parasite of kala-azar in North China. Dr. Hindle is now returning to this country, and it is hoped that further reports on the progress of the investigation will soon be ready for publication.

Dr. Grace, who is investigating filariasis and nephritis, arrived in Georgetown in December, 1926. After overcoming initial difficulties with regard to assistance and supplies, he is now working on the bacterial complications of filariasis and of chronic nephritis.

#### Finance

During the year eight papers were published in the Mathematical and Physical Section, and eight in the Biological Section of the *Philosophical Transactions*, together these parts contain 831 pages of letterpress and 33 plates. Twenty-two numbers of the *Proceedings* have been issued, those in the Mathematical and Physical Section contain 2,724 pages, 92 plates, and three portraits, those in the Biological Section 780 pages, 44 plates, and sixteen portraits.

The Imperial Chemical Industries, Limited, has promised to subscribe £1,000 a year until further notice to help to meet the deficit on the publications account. In 1925 Sir Alexander Pedder bequeathed a portion of the residue of his estate to be used at the discretion of the Society for the advancement of chemical science. The amount realized yields an income of £170 a year, it will be used for the present to meet the expenses of publishing chemical and other papers by the Society. Thirteen applications had been received from societies for grants in aid of publication, eleven grants were made, the total sum allotted amounting to £1,700.

#### PRESIDENT'S ADDRESS

The President, as is customary, began his address by speaking of the Fellows who had died during the year.

#### E. H. Starling

Of Professor E. H. Starling, who was the first of the Royal Society's research professors, he said:

"For more than thirty years Starling has been recognized as an outstanding figure in physiology, and the investigations which he carried out with energy and enthusiasm have effected a clarification of knowledge and a new orientation of ideas concerning a succession of the most important functions of the body. His earliest studies, made like so many later ones in cooperation with his great friend and scientific partner, the late Sir William Bayliss, were directed to analysis of the action of the mammalian heart. Though his activities were for many years directed to other problems, his interest in the heart and the factors regulating its function remained with him always and became again effective in his later years in a series of masterly articles. These he carried out, with a succession of able colleagues and pupils on the mammalian heart, isolated by a method of his own deriving from the vessels of the major circulation and performing its function under conditions which allowed the rate at which the blood entered the heart and the resistance encountered in its ejection to be artificially controlled—the well known 'heart lung preparation'."

In the intervening years he had completed and published, largely with Bayliss a series of researches in which the physical laws governing filtration, diffusion and osmosis through membranes were applied to explain the formation and absorption of lymph. There followed further co-operative investigations with Bayliss on the movements of the intestinal walls, their co-ordination by the local nervous plexuses and their general control by the central nervous system and then—most famous probably, of all their joint researches—their work on the stimulation of pancreatic secretion following the discharge of the stomach contents into the small intestine. This led to the discovery of 'secretin' and the formation of general conceptions of the control of bodily functions by chemical messengers or 'hormones,' embodied in Bayliss and Starling's joint Croonian Lecture before the Society.

During the war and the years immediately following, Starling gave his whole energies to the service of the State, as director of investigations on defence against chemical warfare, as chemical adviser to the army at Salonica and later as chairman of the Royal Society's Food Committee, and as member of the Ministry of Food, and British scientific delegate to the International Food Commission.

When his thoughts and activities were at last free to return to their own natural channels, he began a large and exacting series of investigations in which he combined some of his earlier methods to study the formation of urine under conditions artificially controlled and varied. These researches with many others grew from them, he continued to prosecute during his later years, the Foulerton professorship. He enjoyed the assistance and collaboration of a succession of able colleagues and of many workers from many countries, eager to learn his methods and imbibe his ideas. It might have been hoped that the conditions of freedom from the responsibilities of administration and formal teaching would have enabled him to con-

physical power, but starting with energy and burning with them forbade all thought of relaxation till at length a physique was won by illness, broke and the strain.

By Sir John's death the Royal Society has lost not only a great investigator who has reared one of its chiefs illustrious by his brilliant record of research as Fekulion professor but a fellow who has been generous and efficient, rare to the society, one of its Council and its committee who has been proud of its traditions and joys for its fame and prosperity. He was awarded a Royal Medal in 1913. In and beyond this Society he was a talismanic champion of the claims of research and the interests of his scientific colleagues. Physiology above all was the central interest and enthusiasm of his life. In it faithful and energetic pursuit he had always one end in view, the to quote from his own beautiful Harvard Oration was to attain to a comprehension of the wisdom of the body and the understanding of the heart and thereby to the mastery of disease and pain which will enable us to relieve the burden of mankind.

#### William Einthoven

William Einthoven, the President and, for many two years professor of physiology in the University of Leiden, and Nobel Laureate in Medicine, was elected a Foreign Member of the Society in 1920.

His long scientific career was devoted to the invention and perfecting of physical apparatus of the greatest delicacy and precision for the record and analysis of processes occurring in the living body or having a physiological interest. His string galvanometer, originally devised for recording the fleeting electrical changes which accompany the different stages of the beat of the heart and now in world-wide use in hospitals as well as physiological laboratories, has a found application in a wide range of purely physical investigations.

#### Other Distinguished Fellows

The President also referred to the deaths of Sir Arthur Stimpney, well known for his contributions to paritology, who had been for seventeen years before his death Master of Christ's College, Cambridge, or Professor Sainte Arlhumus (foreign member) director of the Nobel Institute in Stockholm who in 1889 published his famous paper on the theory of ionic dissociation to explain the properties of electrolytes, and of A. A. Lawson, professor of botany in the University of Sydney, who was a selected candidate for the Fellowship, but died before the date of formal election.

Sir E. C. Ruthven next discussed the criterion for the sparse attendance at the ordinary meetings of the Society, it had been hoped to improve it by grouping the papers, but this had not met with much success. In the early days of the Society it had been customary to perform experiments before the Fellows, but this custom had gradually fallen into abeyance, it was proposed to revive it. Portable demonstration tables had been placed in the tea room with connections for water, gas and electric current. It was thought that in every branch of science, but particularly in the biological sciences, there must be many simple experiments and preparations which could be readily shown in such an extemporized laboratory, such demonstrations would be of interest not only to the scientific but to the Society in general.

Sir Ernest Rutherford then turned to a review of the results of investigations carried out in recent years to produce intense magnetic fields and high voltages for general scientific purposes. In concluding his address he referred to the medals awarded on this occasion.

#### The Copley Medal

Of the recipient of the Copley Medal, Sir C. S. Sherrington, Sir O. M. he said:

Sherrington early chose a the special field of his investigations the physiology of the central nervous system. To this during some thirty years he has steadily devoted his great skill in experimental bringing the immense complexities of its function within the range of objective analysis and revealing fundamental plan and orderly sequence in the reflex action by which it controls the activities of the body and continuously adjusts them to the environment. The results of his work have been embodied in a series of some two hundred original monographs, presenting a continuous record of progress in investigation. The various facts have been brought under review and treated synthetically by Sherrington in his now famous *William lectures*. On the integrative action of the nervous system. In these he deals with the coordination and guidance of the muscular rigidity which appears when the higher brain is removed with the co-ordination of muscular movement by a spread excitation and inhibition of antagonistic muscles with the rhythmic phase activity which the cord produces in the reflex arc and with the more recent and with the apparatus of a purposeful character which the integrative action impresses on many forms of reflex response. During his recent years our own *Proceedings* have been steadily with the progress made in the nerve system, the function of the central nervous system by Sherrington, Laid and by

pupils using the methods which he has created and building on the foundations which he has laid.

The influence of Sherrington's investigations has spread far beyond the limits of his own laboratory and has inaugurated a new era in neurophysiological investigation throughout the world. In this connexion we may fittingly pay a tribute to the memory of one of the most eminent among those who have drawn inspiration from Sherrington's work and from personal contact with him, Sir Rudolph Magnus of Utrecht whose early death in this year the whole world of science deplores found there the impulse to his own original and far-reaching investigation the results of which he embodied in the Croonian lecture to this Society two years ago on *Animal posture*. In every civilized country in the neurophysiological clinic as well as in the laboratory of physiology and of experimental psychology the influence of Sherrington's work is felt giving the clue to the understanding of many of the motor symptoms of nervous disorder and holding out promise that even the higher functions of the central nervous system will not remain permanently beyond the reach of man's experimental inquiry.

#### The Royal Medals

Or Sir Thomas Lewis to whom one of the Royal Medals has been awarded, he spoke as follows:

From 1911 onwards to the present day Sir Thomas Lewis has taken a leading part in the remarkable growth of our knowledge of the mammalian heart beat which has been one of the conspicuous scientific achievements of the period in question. Until he began his work nothing was known for certain as to the relation of the peripheral structures known to anatomy to the origin and propagation of the beat of the heart. Lewis's researches enabled him to locate the point of origin of the beat and to plot out the course of the wave of excitation over the ventricles and auricles of mammal. By extending these observations to the hearts of representative vertebrates he was able to compare the modes of spread of the wave with the peculiar forms of the electrocardiogram and thus to appreciate clearly the meanings of the several deflections. Further extension to diseased hearts led to the interpretation of the abnormalities of the electrocardiographic record.

In 1911 Lewis was able to show that as Cushing had previously suggested, certain cardiac irregularities are due to fibrillation of the auricle and his later clinical and experimental work on auricular fibrillation and flutter suggested that the irregularities are due to the formation of an ebb and a circulating wave of contraction in the auricles. In this peculiar field of physiology and pathology of which great importance to medicine Lewis's researches have replaced a mass of scattered suggestive observations by a coherent and established theory. His book on this subject which is necessary and based to a large extent upon his own observation is recognized as authoritative throughout the world.

Quite recently Lewis has published another book which embodies the result of investigations of the peripheral circulation upon which he has been engaged during the past two or three years. The response to other and of stimulus closely resembles that induced by injection of histamine into a puncture and Lewis produces strong evidence that even the response to pressure is due to the liberation in the tissue of a chemical compound which is not actually histamine, but which has about the same effect.

In this investigation which may be taken as a model for the application of exact method to human physiology and pathology Lewis has shown the qualitative accuracy of experiment and exact reasoning which are so conspicuous in his work up to the heart's action.

#### The Buchanan Medal

Or Professor Major Greenwood, to whom the Buchanan Medal is presented, he said:

Dr Greenwood, Medical Officer (Medical Statistics), Ministry of Health, Professor of Epidemiology and Vital Statistics, University of London (London School of Hygiene), Chairman of the Medical Research Council Statistical Committee and Statistician to the Lister Institute, is especially distinguished for the statistical study of medical subjects having applied the statistical method to the elucidation of many problems of physiology, pathology, hygiene and epidemiology. He has been pre-eminent in encouraging and developing the use of modern statistical method by medical laboratory investigators and in securing the adequate planning and execution of field investigation. He is almost unique in possession of both the medical knowledge and mathematical ability which are essential in the researches. Dr Greenwood is the author (with Professor E. L. Collis) of a book on *The Health of the Industrial Worker* and of numerous biometric studies dealing with the causation, prevention and treatment of disease.

#### The Hughes Medal

The Hughes Medal has been awarded to William David Coolidge, a distinguished member of the scientific staff of the General Electric Company of America. Or him the President said:

Dr Coolidge is a great debt to Coolidge for the invention and production of a new type of x-ray tube called by his name of great flexibility and power which has produced a great increase in the use of x-ray radiology both in numerous scientific researches. In the last few years he has applied his scientific and technical knowledge to the construction of high speed cathode ray tubes which can be used in the x-ray through a thin window as in Coolidge's pioneer experiment thirty years ago. Such researches are of great importance to science in this period to provide a new method of obtaining a more powerful source of x-rays and high speed atoms of matter for experimental investigations.

# British Medical Journal.

SATURDAY, DECEMBER 3RD, 1927.

## THE ASSOCIATION IN 1927

MEDICAL practitioners who, for reasons that may seem good to them, are not now members of the British Medical Association, and final year students who hope soon to become qualified, would do well to study the middle pages of the SUPPLEMENT to our present issue, where they will find a brief account of the aims of the Association, its work and organization, and of the privileges and responsibilities of membership. If figures speak more forcibly to them than words, they should turn to the chart showing graphically the number of members in each year since 1877. A total membership to day of 33,600, and a net increase of more than 13,500 since the war, are facts of the kind that point their own moral. Continued growth year by year, not only at home but throughout the British Empire, is a sign of vigorous life in an organization now nearing its hundredth anniversary. There are other standards of success, and the Association is very willing to be judged by them, though the work it does for the individual doctor, for the profession at large, and for the public cannot be measured by simple tests and put down in a diagram. The occasion may, however, be taken to look back over the year that is closing and recall some of the manifold ways in which the Association in 1927 has tried to fulfil its duty.

The first of the three main objects of the British Medical Association is to promote the medical and allied sciences, the second is to uphold the honour and interests of the profession, and the third is to encourage good feeling among its members. These sides of its work—scientific, political, and social—are organized on distinct lines, but are not sharply cut off, and at the Annual Meeting they overlap a good deal, both in space and time, with benefit to all. The Annual Meeting is the central event in the Association's year, and by general consent the great professional gathering in Edinburgh last July, under the presidency of Sir Robert Philip, was one of the most interesting and most enjoyable ever held. The Scottish capital, with its historic associations, its natural and architectural charm, and its world-renowned medical school, is an ideal place for a medical congress, and the celebration of Lister's centenary there during the same week added to the interest of the occasion. Full reports of the proceedings in the scientific sections at Edinburgh have appeared in our columns during the past four months, and we hope soon to complete their publication. These important papers and debates, however, are only part of a great volume of work on behalf of medical science carried out during the year through the machinery of the Association. Clinical meetings have been held periodically by many Divisions and Branches at home and abroad, lectures on medicine, surgery, and obstetrics have been given for the Association in various parts of the country by leaders of the profession, the Library has responded to the growing demand upon it from members up and down the country, prizes, scholarships, and grants in aid of research have been awarded by the Council on the advice of the Science Committee, and encouragement has been

given to post-graduate education and to collective inquiries into everyday problems of practice. Since all these phases of the Association's work for science have been reflected in our columns month by month, it may be worth noting that in 1927 this Journal completed its seventieth year of publication under the title *British Medical Journal*, and the eighty seventh year of its life as the weekly organ of the Association.

In support of the honour and interests of the profession the Association has been no less active than in the promotion of science. To secure in every field of medical practice the conditions essential to the provision of an increasingly effective service to the community, to improve old and find out new methods of co-operation between the profession and the numerous statutory and voluntary bodies which minister to the common health, and to preserve through every fluctuation of the changing social order and in all schemes for extended health services the economic basis of medical efficiency—this is a task which could be undertaken successfully by no smaller or less representative body than ours. Hence the importance of ensuring that the voice of every section of the medical profession has its due weight in the counsels of the Association, and the significance of the new scheme allowing for a special form of group organization where this seems to be called for. Nor must it be forgotten that through the Overseas Branches the experience of the parent body is made available for our colleagues in the Dominions and Colonies. The Australian Federal Committee, in tackling the problem of health insurance, profits by the hard-won wisdom of insurance practitioners in Great Britain, and lends that wisdom to the Federal Government. The Medical Association of South Africa finds the path to professional solidarity in the Union within the British Medical Association, under a constitution adjusted to modern needs by a long process of evolution. The medical services in the Crown Colonies profit by the Association's experience of hospital problems, as well as by the existence of a body able to take up service difficulties with the Colonial Office.

In the field of health insurance at home, where the Insurance Acts Committee's scheme for a revised disciplinary machinery marks a definite stage in the development of the national system, in the struggle to free English lunacy law from the bonds of the ignorant suspicion which hinders adequate treatment of the sick in mind, and exposes the doctor to harassing persecution in the discharge of his duties towards the patient, in schemes for the reform of the Poor Law, and in many other directions, the Association has met increasing calls upon its resources, and will continue to find an ample field of service to the public and the profession. A scheme for making more effective its contribution to public education in health matters was approved at Edinburgh, the formulation of a middle class hospital policy has been undertaken, and a comprehensive review of the relations between private practice and the health services offered to the public by statutory and voluntary bodies has been begun. The increasing proportion of public health appointments advertised at the Association's scale rates of salary is the justification of a policy endorsed in 1925 not without doubt and anxiety.

As in the arena of public policy, so in the promotion of individual interests the work of the Association has gone forward. The sweetening of professional relationships through friendly advice and arbitration in

cises or dispute is part of the daily routine or the Association's headquarters, so, too, is intervention to protect holders of salaried medical posts from arbitrary action on the part of employing bodies, and advice in all the perplexities of professional life. Through the Medical Insurance Agency, which has its offices in the Association's House and receives much other assistance from the Association, and now through the British Medical Bureau and an increasing volume of medical agency work undertaken by local bureaux under the auspices of Divisions and Branches the more material interests of members are cared for, whilst through the efforts of the Charities Committee a step at least has been taken towards the removal of a standing reproach to the profession.

The work of the British Medical Association is not to be defined or evaluated within the compass of a brief review. If we have conveyed any impression of its nature and scope it will be clear that the social activities of the Association are the natural outcome of fellowship in such service as it renders to the profession and to the public. This fellowship is in itself the best guarantee of the healthy professional spirit which for ninety five years the Association has sought to maintain.

### THE MEDALS OF THE ROYAL SOCIETY

THE award this year of three of the chief medals in the gift of the Royal Society to members of our profession makes this an *annus mirabilis* for British medicine. The names were mentioned here three weeks ago and the President Sir Ernest Rutherford in his address at the anniversary meeting of the Society on St Andrew's Day (p. 1038) stated the reason for the selections in terms which must give the greatest pleasure not only to the recipients but to all of us. The work of both Sir Charles Sherrington and Sir Thomas Lewis, though physiological has been so precise and conclusive—so clean-cut—that it has at once found application to clinical medicine, while Professor Major Greenwood has with mathematical acumen helped perhaps more than anyone to induce a cool and calm study of vital statistics.

Although no medal is given with it it may be permitted to mention here that a Conway Evans Prize has been awarded this year. Dr Conway Evans who was a Member of the Royal College of Physicians and medical officer of the Strand District died in 1892 bequeathing the residue of his estate in trust to the President of the Royal Society and the President of the Royal College of Physicians directing that the proceeds should be given from time to time to some person who in their opinion has made some valuable contribution or addition to science. The fund was transferred into the trust of the Presidents in February, 1925. The testator gave to the Presidents full discretion as to the date and amount of any award and they have now agreed that the first award amounting to 500 guineas shall be made to Sir Charles Sherrington; this decision was announced at the anniversary dinner on November 30th.

The awards this year recall to us once again the great services the Royal Society, holding the balance with stern impartiality, has rendered and continues to render to mankind in general and our race in particular. In its early days the Society notwithstanding the patronage of King Charles II was the object of much ridicule by the would-be wits of the day and even so great a writer as Jonathan Swift condescended in his *Laputa* to satirize and scoff at its early investigations. More than a century later the inimitable

Boz seems to have thought the British Association too glib for his broad humour when he cast ridicule upon the doings of the Mudfog Association. But neither Swift nor Dickens could harm the subjects of their misplaced humour, they have since flourished exceedingly.

The Royal Society of London—to give it its full title—does not now concern itself directly with the arts of medicine or surgery. Its honours are given for good and original work in any science but on work of this order all progress in the healing art ultimately depends. As physiology and anatomy are closely associated with medicine and constitute, indeed, what used to be called the institutes of medicine, it is not surprising that among the recipients of the medals awarded by the Society a number of members of our profession should be found. This year indeed we have our full share. Sir Thomas Lewis receives a Royal Medal for his researches upon the vascular system following upon his earlier work on the mammalian heart beat. Sir Charles Sherrington the Copley Medal, the greatest honour that the Society has in its gift for his distinguished work on neurology and Professor Major Greenwood the Buchanan Medal for his statistical researches and other work in relation to public health. All of these honours have been thoroughly well earned and worthily bestowed and then recipients have our warmest congratulations. Yet another medal has been awarded for work in a department of science which has of late years come so closely to concern medical and surgical practice, and although its recipient Mr William D Coolidge, is not a medical man his name has become a household word among radiologists and all those who are concerned in any way with x-rays. It is for his work on the x-rays and the development of highly efficient apparatus for their production that the award of the Hughes Medal is made.

The history of the medals of the Royal Society is of some interest. For the first forty seven years of its existence the Society like Kipling's Fuzzy-Wuzzy hadn't got no medals nor rewards for it was not till the year 1709 that one of its Fellows Sir Godfrey Copley of Sprotborough Yorkshire, baronet dying bequeathed to Sir Hans Sloane Bt and Abraham Hill Esq the sum of one hundred pounds in trust for the Royal Society of London for improving natural knowledge to be laid out in experiments or otherwise for the benefit thereof as they shall direct and appoint. We do not suppose that Sir Godfrey Copley had any motive in this bequest less worthy than a love of science and of the Society to which he had for many years belonged but if he had intended to make his name illustrious for centuries he could hardly have chosen a better or surer way or doing so, even had he instead adopted Hamlet's advice to build churches. For twenty six years the interest of the bequest was given to the curator of the Society Dr (or laws) Desaguliers for various experiments made before the Fellows a practice now to be revived in a modified form. In 1736 however it was applied to purchase a gold medal to be awarded to the author of the most important scientific discovery or contribution to science by experiment or otherwise not confining the benediction within the narrow limits of any particular country much less of the Society itself. With few exceptions a Copley Medal has been awarded every year since 1736. Compared with the Royal Medal the Copley has not been bestowed upon many medical men. In 1787 John Hunter received it for his papers on the ovary and on the identity of the

dog, wolf, and jackal species, and on the anatomy of whales. It was awarded to Astley Paston Cooper in 1801 for a research into the effects of the destruction of the membrana tympani of the ear. Everard Home and Benjamin Brodie both received the honour, as did Richard Owen. Joseph Lister had it in 1880, Sir Joseph Hooker in 1887, and T. H. Huxley in 1888. Sir E. Sharpey-Schaefer was given this medal in 1924, and Sir F. Gowland Hopkins received it last year. It may be noted that in 1864 it was awarded to Charles Darwin, whose doctrine has so profoundly influenced the progress of medicine.

The reputation of King George IV has of late years somewhat improved under the treatment of annalists, but it is still not such as to be able to dispense with any credit that can be attached to his name. Therefore it seems well to recall attention to his good deed of instituting the Royal Medals of the Society. It is probably but a coincidence that the two most heterodox kings since the Tudors should have sought to benefit science. Charles II seems to have been easy going and good natured when his own pleasures were not interfered with, and to have been stung at times by curiosity as regards natural phenomena. What good influence induced George IV to found the Royal Medals we know not, for there is no evidence that he took any interest in experiments or inquiries in natural philosophy. Be that as it may, in the year 1825 Sir Humphry Davy, then President of the Royal Society, received a letter from Sir Robert Peel announcing His Majesty's intention "to found two gold medals of fifty guineas each, to be awarded as honorary premiums under the direction of the President and Council." Resolutions were shortly afterwards carried by the Council in accordance with the King's wishes, but when in 1830 he died no medals had yet been forthcoming, nor their equivalent in money. The foundation lapsed on the demise of the Crown but King William IV restored it, and at length in 1833 the ten Royal Medals in aureum were distributed, the first having been awarded in 1826 to John Dalton for his work on the atomic theory. There were neither awards nor medals for the years 1831 and 1832, during which the original foundation had lapsed and King William had not yet restored it. His foundation was not retrospective, and the series of awards began afresh in 1833 with A. P. De Candolle, the botanist, and J. F. W. Herschel the astronomer. Since that date two Royal Medals have been awarded every year, the foundation having been restored by each successive sovereign on his accession. Awards of these medals are submitted by the President and Council to the King for his approval before they are announced.

A number of members of the medical profession have been honoured with these medals, generally speaking for researches in physiology or (less often) pathology. In 1829 Charles Bell received a Royal Medal for his work on the nervous system, in 1839 Dr. Martin Barry received it for his demonstration of spermatozoa in the ovum, and in 1842 William Bowman for his work on the kidney. Among many subsequent awards were those to Richard Owen, Benjamin Brodie, T. H. Huxley, Joseph Hooker, W. B. Carpenter, Loekhart Clarke, G. J. Alcock, Joseph Lister, W. H. Flower, Bardon Sanderson, David Ferriar—<sup>1</sup>a veterinarian who is still spared to us—and Victor Horsley. Professor Sharpey-Schaefer received the medal in 1902 and Sir C. S. Sherrington, who now is awarded the Copley, was given the Royal Medal in 1905. Henry Hurd, Ronald Ross, W. M. Bayliss, G. Elliot Smith, E. H. Starling, J. S. Haldane, and H. H. Dale were worthy predecessors

of Sir Thomas Lewis, the latest medical Royal Medalist.

The Buchanan Medal, which is well earned by Professor Major Greenwood, has a much shorter history than those above named. It is a gold medal of the value of £20 provided by a fund of £276 10s. raised in 1894 in honour of Sir George Buchanan, principal medical officer of the Local Government Board, who died in 1895. It is awarded every five years for distinguished service in hygienic science and practice. The first medal was given by the subscribers of the fund to Lady Buchanan. Subsequent medalists have been Sir John Simon, M.D., Dr. Monckton Copeman and William Henry Power, Surgeon General Gorgis, Sir Almoth Wright, and Sir David Bruce.

The Hughes Medal commemorates David Edward Hughes, who died in 1900 and left between £300,000 and £400,000 to London hospitals. He was the inventor of a type printing telegraph, of the microphone, and of the telephone induction balance. The medal bearing his bust is awarded annually, together with the balance of the income of the fund, which is a substantial amount, as the reward of original discovery in the physical sciences, particularly electricity and magnetism. The Royal Society has also in its gift the Rumford, Dawson Davis, and Sylvester Medals. The first named was founded in 1796 for research into heat and light by Sir Benjamin Thompson of Rumford, New Hampshire, an American loyalist who was driven out of New England and became a count of the Holy Roman Empire after long serving the Elector of Bavaria. He is perhaps best known as the founder of the Royal Institution. The Dawson Medal, which is accompanied by a grant of £100, is given every alternate year "in reward of work of acknowledged distinction (especially in biology) in the field in which Mr. Dawson himself laboured." A. R. Wallace, Sir Joseph Hooker, and Prof. Sir T. H. Huxley, Dawson's lifelong friends, were awarded the first three medals. Later recipients have been physiologists and comparative anatomists, but not medical practitioners. The Davis Medal is given for chemical, and the Sylvester for mathematical, research.

#### HYPOGLYCAEMIA

The intensive study of blood sugar that was initiated by the discovery of insulin has revealed a bewildering number of substances that can produce hypoglycaemia. In 1923 Collip<sup>1</sup> showed that a substance which he named glucokinin could be obtained from a great variety of plant tissues. This substance reduced the blood sugar in normal and in depancreatized animals. Collip suggested that it was a plant hormone that played an essential part in the carbohydrate metabolism of plants. Peptides have recently been shown to contain a substance which can produce hypoglycaemia, but the activities of peptides from different sources vary enormously. These results are of interest in view of the recent claims made on behalf of bilberry leaf extract. This was shown by Mark and Wagner<sup>2</sup> to reduce alimentary glycosuria and hyperglycaemia in dogs, and also to reduce glycosuria in diabetic patients. The substance was named myrtillin. Allen<sup>3</sup> has studied the properties of this substance and has found it to produce striking and uniform benefit in diabetic dogs and was also found that its use in human diabetes permits great reductions of the dose of insulin. Myrtillin is equally efficacious if given by mouth or subcutaneously and even the largest dose no

<sup>1</sup> Collip *Journ. of Biol. Chem.* 56: 51, 57, 65, 53, 163, 172.  
<sup>2</sup> Mark and Wagner *Journ. of Biol. Chem.* 92: 253, 1927.  
<sup>3</sup> Allen *Journ. Amer. Med. Assoc.* 83: 577, 1927.

stated to be non-toxic. Allen states, however, that a considerable proportion of failures must be expected, especially in the severest cases and in young patients. The Council of Pharmacy of the American Medical Association has published a preliminary report.<sup>1</sup> This report is very guarded in its statement, but points out that no satisfactory method of standardization has been evolved. This is important, because the chemical nature of mytilin is unknown, and it has not yet been obtained in a pure state. General interest in the possibility of reducing the blood sugar in diabetes by oral administration of drugs has been increased during the last year by the introduction of the substances 'synthilin' (Frank) and 'glukhormant' (von Noorden). About this last-named substance Dr. Dale and Professor von Noorden have a curious story to tell this week (p. 1027). A considerable literature has already arisen about synthilin and mytilin, and there seems to be a general agreement that they will frequently reduce glycosuria and hyperglycaemia in mild cases of diabetes. On the other hand many observers have reported a rather alarming frequency of toxic symptoms, particularly in the case of synthilin. There appear, therefore, to be a wide range of substances obtainable from vegetable and animal tissues that can reduce the blood sugar both in normal and diabetic subjects. Several of these substances appear to produce benefit when given by the mouth in mild cases of diabetes. In no case, however, has any substance been found which can rival insulin either as regards potency or certainty of action.

#### EPSOM COLLEGE SANATORIUM

RATHER less than a year ago we referred in a leading article (December 18th 1926, p. 1187) to the need of providing a modern sanatorium for Epsom College and more adequate isolation and accommodation. Attention was called to the regrettable fact that the only public school which has as a primary aim the provision of special facilities for the sons of medical practitioners is demonstrably behind the times as regards its equipment for dealing with epidemic outbreaks. Moreover the building at present in use is ill adapted for the purpose of treating illness on modern lines in an economical way. The successful efforts made during recent years to raise the standard of the school teaching to the highest level have resulted in an increased entry of boys, which has, however, accentuated the need of better sanatorium facilities and might have led to serious consequences had not the school preserved its excellent record as regards health. We publish at page 1035 of this issue an illustrated description of the new sanatorium which will contain twenty beds for non-infectious cases and thirty beds for infectious cases with ample accommodation for the nursing and domestic staff. Those familiar with the college will realize that in designing the building care has been taken to choose the best available site in order to secure economical administration and the full employment of such natural therapeutic agencies as sunlight and fresh air. A combination in one block of sanatorium and isolation departments is a commendable feature and the danger of infection is met by providing separate entrances and exits for the two divisions. The cost of the building is expected to be £25,600, a little higher than was previously estimated. Towards this sum of over £4,000 has already been received, and a list of donations appears at page 1037. At least £15,000 is required before the actual work of building is begun, and in this connexion we hope that the letter published at page 1035 over the names of Dr. Raymond Crawford, chairman of the council of Epsom College, Sir William Hale-White, the treasurer, and Dr. Arnold London, chairman of the Sanatorium Committee, will be read with sympathy and kindle a generous and speedy

response. Donations to the 'Sanatorium Fund' should be sent to the secretary at the Epsom College office, 49, Bedford Square, W.C.1.

#### PHARYNGEAL AND LARYNGEAL POUCHES

At a meeting of the Royal Physical Society of Edinburgh on November 21st Dr. Douglas Guthrie read a paper on 'Pharyngeal and laryngeal pouches in man and animals.' Pockets ('granules') were, he said, sometimes artificially produced by criminals in India, by means of a lead disc attached to a string, it was retained in position continuously, and served to deepen the normal hollow (sinus pyriformis) at the entrance to the larynx, and the pouch which was thus gradually formed became a safe hiding place for coins or precious stones. This pouch differed in site and origin from the pharyngeal pouch, or diverticulum, which occasionally developed behind the larynx, the latter was of the nature of a hernia and sometimes demanded surgical attention. It was interesting to note that in the pig a pouch was normally present at this point in the posterior pharyngeal wall but no such structure was found in other domestic animals. Other pouches such as those found within the larynx were of interest to the comparative anatomist. In man there was a depression the laryngeal ventricle just above each vocal cord and from this a little pouch or sacculus extended upwards for a variable distance. In the gorilla and chimpanzee this extension, uniting with its neighbour of the opposite side, reached as far as the root of the neck. In other monkeys the two united sacculi occupied a large cavity in the larynx. Absent in the sheep and ox, the ventricle and sacculus were found in the dog and pig while in the horse the sacculus part was relatively large. Advantage was taken of this fact in the operation of ventricle-stripping to cure 'roaring' in horses. The function of laryngeal pouches was uncertain. They might serve to lubricate the vocal cords or might act as resonating chambers, or might simply be the degenerate remains of the accessory air reservoirs, such as exist in the frog and in birds. The communication was illustrated by specimens and lantern slides, and by a series of casts showing the shape of the sacculus in various species.

#### THE AUTOBIOGRAPHY OF AN ACROMEGALIC

Books descriptive of their own maladies by medical authors are not numerous. Some years ago Dr. Edward Liveing, who suffered from migraine, wrote a book which is a classic on that subject, and in 1912 Dr. Leonard Mark produced a notable work entitled *Acromegaly: A Personal Experience*,<sup>1</sup> and to it he has recently added a sequel under the title of *The Apologia of an Acromegalic*. Taken together these two publications give a pretty full account of the life of a man of ability who has now passed the proverbial three score and ten years and has suffered from symptoms of acromegaly at that time unrecognized, since the age of 24. Apart from its medical interest, Dr. Mark's book will always be valuable as the record of the career of a member of the professional class, who was brought up till the age of 20 in the South of France and has since lived in London and shared in its medical life. It is of interest to note that, despite many distressing symptoms, Dr. Mark did not himself recognize the nature of his trouble until years after it was obvious to his medical friends, and after Dr. Pierre Marie who first described the disease had picked him out from a crowd of bystanders as a typical acromegalic. Dr. Mark tells us in his last paper that when in 1912 his book was published he looked upon it as his swan-song and anticipated an early death. Now, fifteen years later, he accepts the opinion, given by

<sup>1</sup> London: Baillière Tindall and Cox.

<sup>2</sup> *Medical Press and Circular*, October 5th and 12th, 1927.

<sup>1</sup> (Report) *Journ. Amer. Med. Assoc.* 89, 1607, 1927.

Sir William Osler in 1919, to the effect that the disease had then ceased to progress, and that he was suffering only from the effects of the permanent changes produced by it. But Dr. Mark has not been content with the study of his own case alone. He gives much interesting information on the disease as he has observed it in others, and on cases in the London Poor Law infirmaries, he has written an account of the "Governor" of Scarborough Spa 200 years ago, whom he has satisfied himself, from pictures and descriptions, was an anomegale. Dr. Mark does not, it seems, regret that he was born rather too late to profit by the operation devised and carried out by Professor Harvey Cushing, for, as he asks, "Who can tell whether to-day I am better off?" We congratulate Dr. Mark upon his unconquerable soul, and on the pluck with which, through half a century, he has fought his disabilities and made his disease a subject for interesting investigation and study. Long may he survive to take those omnibus rides into the suburbs which he has found so refreshing, and may his closing aspiration, in the form of the following quotation from Montaigne, find fulfilment in the end: "I would have a man to be doing, and to prolong his life's offices, as much as lieth in him, and let death seize upon me, whilst I am setting my cabiges, cruclesso of her dart, but more of my imperfect garden."

#### BRILL'S DISEASE AT MARSEILLES

For the last three or four years the Mediterranean coast of France, especially in the neighbourhood of Marseilles, has experienced an infectious exanthematous epidemic of an unusual kind. Reports on this disease have been made to the Académie de Médecine in Paris by physicians of Marseilles—me by Dr. Olmer, presented to the Académie on July 12th, and another by Drs. Boinet and Jean Prier, which is published in the *Bulletin de l'Académie de Médecine* for October 4th. There appears to be a common opinion that the disease is a benign form of typhus, similar to the outbreak in New York in 1898, to which the name Brill's disease has been given. In Marseilles it has attacked persons in all classes of life and in many different neighbourhoods, but it has been rare to find several patients in one house. Some of the patients had been in contact with foreigners, especially with Orientals. The infection could not be traced to parasites, the sick persons were quite free from lice. The results of bacteriological investigations were negative, agglutination to *proteus* X<sup>19</sup> of Weil-Felix never occurred. The onset is sudden, with headache and rapid rise of temperature. Sometimes there are abdominal pains and foetid diarrhoea. The throat becomes reddened as in scarlet fever, and small ulcers may form on the pillars of the fauces. The rash appears about the third day, it begins on the lower extremities, and extends upwards until it reaches the face. It consists of numerous spots, pink at first but becoming violet-coloured, though hardly ever ecchymotic. After about a week the spots begin to get pale, those on the lower extremities being the last to disappear. As the spots pale the temperature gradually falls. In nearly all cases a little black scab is found at some spot on the body, and the observers think that this may mark the site of inoculation with the disease. Constitutional symptoms are not severe, and albuminuria is absent, but the liver is enlarged, and occasionally there is some congestion at the bases of the lungs. Nerve symptoms are common, and resemble those seen in meningitis. So far the only fatal case has been in a patient, aged 15 years, who had some previous myocarditis. Drs. Boinet and Prier seem to be doubtful whether the epidemic is really one of Brill's disease, but Dr. Vetter in the discussion following the communication regarded the diseases as identical though he admitted that the fever and eruption formed part of the usual symptoms of dengue fever.

#### THE DECLINE IN LEAD POISONING

That lead poisoning has been declining in this country during the last thirty years is common knowledge among the medical profession. This statement, however, rests rather upon individual than collective experience. Dr. Frederick L. Hoffmann, consulting statistician Prudential Assurance Company, America, who has unusual opportunities of obtaining data upon a large scale, confirms the statement as regards his own country and ours. The information comes opportunely, and ought to be helpful to all who are interested in the social and economic problems of industrial plumbism. The decline in lead poisoning is the result of regulations introduced over thirty years ago. Within recent times an appeal for reforms has been made and a widespread call for prohibition heard, but in these countries wherein prohibition has been adopted there have been, we are informed, serious economic consequences, alike to the industry and the workers. The British Government, before resorting to prohibition, took the wiser course of insisting upon fresh regulations being tried, involving, particularly in the case of house painters, wet instead of dry methods of cleaning old painted surfaces. In the United States the deaths from lead poisoning declined during the period 1910-24 from 2.5 per million to 1.4, and this in every section of the country investigated. In the U.S. navy the case rate declined from 0.5 per 1,000 in 1913 to 0.05 in 1924, in New York City it fell from 4.5 per million in 1904 to 1.1 per million in 1924. Hoffmann reminds us that death from plumbism occurs among many of the population who are not industrially brought into contact with the metal—for example, children who have sucked lead-painted toys, and women engaged in home work. In painters there were 407 deaths in the five years ending 1913, as against 360 during the five years ending 1923, the average age at death of painters meanwhile had risen from 50.6 years to 51.9 years during the same period. Taking the cases reported to the authorities, the average age at which illness developed was 30.3 years—a circumstance which shows that lead poisoning is a non-fatal form occurs comparatively early in a painter's life. In the United States the largest number of cases of plumbism occur among workers in electric storage battery plants. Of 920 cases in all trades, 50.1 per cent were in men engaged in this industry, as against 29.3 per cent in painters. The malady appears in electric storage battery workers early (33.2 years). In Germany the rate of chronic lead poisoning in these workers is 1 per cent, in Great Britain 3 per cent, and in the United States 18 per cent. The general decline of industrial plumbism in the United States is attributed by Hoffmann to the higher standard of living among the wage-earners, improved nutrition increasing their resistance and causing them to be less liable to fatigue. Possibly the difficulty of obtaining intoxicants may have a helpful influence, also the better ventilation of factories, periodical medical examination of the workers, and rational factory legislation. In the Utah mines lead poisoning occurred with considerable frequency when the men were working in the carbonate ores. Of 2,762 patients admitted into the Miners' Hospital for all causes, 8.3 per cent were suffering from plumbism, but, taking the calculated rates per 1,000 men in the chief lead producing regions of Utah, the numbers of cases were 62.7 for 1919, 34.7 for 1920, 21.7 for 1921, 17.7 for 1922 and 10.0 for 1923. As regards lead poisoning in potteries, Hoffmann remarks that in the light of his knowledge, extending over thirty years, of conditions in American potteries, the incidence of the disease has been reduced to such negligible proportions as to be, practically speaking, a thing of the past. The mortality rates of the United States and those of England and Wales are contrasted. In 1925 the chief inspector of factories reported 13 deaths in Great Britain from lead

personnel, not including painters, is against 32 for 1924. The total number of cases of plumbism notified declined from 486 in 1924 to 326 in 1925. In the pottery, while the number of cases notified remained the same (47) for the two years mentioned, the deaths fell from 18 to 5. British statistics thus confirm American experience as to the marked decline of the hazard in industries in which lead is used. Hoffmann drew attention to the subject of 'lead absorption' and 'lead poisoning.' The two are not one and the same. Dr Kelso examined 65 apparently healthy American workmen taken at random, and found lead in the urine or the feces, or in both, but not one of the men was suffering from plumbism. At present there is no known quantitative expression of lead excretion in man which is significant of impending or present plumbism.

#### THE GENERAL MEDICAL COUNCIL

THE winter session of the General Medical Council lasted only four days. It seemed likely that the business would extend into a fifth day or even longer but the postponement of a penal case enabled the Council to complete its business in its unusually short session. Sir Norman Walker, at the close of the proceedings said that the saving of a day would be very gratifying to the trustees for it meant that the Council would be in pocket by some £250. This figure gives some substance to the common assertion that for the time it is sitting, the Council is an expensive judicial body. A little calculation shows that its proceedings cost one pound a minute, this is much in fees and allowances to members and does not take account of its continuing expenses nor of the expenses of the clerk who appears before it. The disciplinary cases on this occasion, apart from those postponed for judgement from previous sessions numbered only seven, and none of them raised any fresh points of professional interest. Five out of the seven were consequent upon court convictions for drunkenness or offences arising out of alleged drunkenness, and the other two cases were charges of adultery during private moral delinquency. The names of both the practitioners who had figured in Divorce Court proceedings were erased. The Council of course takes no cognizance of adultery as such but only of professional relationship precedent to or contemporaneous with such adultery. Both the cases emphasized the fact that the Council does not regard itself as bound to proceed strictly along the lines followed in court or law with regard to the admission of evidence. The legal representatives of the practitioners in both instances protested against being called upon to meet documents, such as letters, diaries and prescriptions put in at the last moment after the sworn declarations regarding the complaint had been made. They contended that in a court of law such a proceeding would not be allowed, and that a defendant and his representing him should know beforehand exactly what he had to meet. The objections were however overruled. It is well, therefore for all who may come before the General Medical Council to be aware that it does not regard itself as bound to observe the rules and precedents which obtain in ordinary courts of law. In none of the cases in which drunkenness was a feature did the Council proceed to the extremity of erasure but in three or them judgement was postponed to a later date when the practitioners in question will have to bring forward to the tribunal from their professional brethren as to their conduct in the interval. The non-disciplinary business of the Council occupied only a brief morning. It included the presentation of a final report by the Education Committee on the progress throughout the country towards the readjustment of the medical curriculum in accordance with the resolutions of the Council adopted in 1922. This report is a volume of nearly 200

pages, but its presentation led only to a short discussion, mostly mundanely in the press gallery. The acoustics of the Council chamber have lately been improved, but the press is unfortunately situated in a gallery, beneath which many of the speakers address the Council, in view of the press, and often unheard. That this press may be useful to the General Medical Council was proved by the chairman of one of the committees, who, in presenting a report, begged the new paper reporters to take special note of what he had to say. This is probably the first case on file that the "stringers in the gallery" have ever been addressed other than in the words, "You are requested to withdraw."

#### THE HUMAN FACTOR IN INDUSTRY

THE EARL OF BILBOUR presided over an interesting meeting of the National Institute of Industrial Psychology on November 25th, when a number of the Institute's investigators described how psychology entered into the experience of the factory. Lord Bilbour said that the industrialist who is the material element in his organization with the greatest care, and with every regard to their adaptability to the end in view, but the machine so designed was put in charge of human beings with regard to whom no particular selection or study had been made. Even if the best-intentioned person were put in a position unsuited to his tastes and abilities he would be not only unhappy and inefficient. In a subject such as industrial psychology the interests of employers and employed were obviously identical. He was inclined to believe that such interests were always in the long run identical but there could be no doubt at all that in the field of psychology what was good for one was good for the other. The Industrial Fatigue Research Board, a branch of a much larger body the Medical Research Council was carrying on valuable work, but a Government department could not be expected to deal with the special details of a particular industry, and this was where the National Institute of Industrial Psychology became so useful. The Fatigue Research Board dealt with fundamental problems while the Institute endeavoured to apply psychological science to the actual detailed necessities of particular firms or industries and he noted that the present staff of the Institute had made special studies for forty-two firms covering twenty-six industries. Following Lord Bilbour's speech a number of inquiries who had been advising on factory plant gave brief accounts of their experiences and observations. One of them said that while an electric motor would work almost as well in an arctic as in a tropical environment and had limits of output which could be defined with mathematical accuracy and movements that preceded with geometrical precision, human beings were of infinite variety, and the reactions of the same individual to different circumstances covered an almost unbelievable wide range. Another investigator said that his investigations had shown that individuals differed considerably in the extent to which they found a given task tiresome or account of its monotony. Some preferred the monotonous tasks because these gave them the opportunity for day-dreaming. Generally, the higher the intelligence of the worker the more repugnant was the repetition task. The advice which the Institute had given in order to avoid monotony was to introduce rest pauses, to use music and singing where possible to improve drab surroundings by attractive pictures and the like, and most important of all to adopt periodical changes of work.

DR L. S. T. BURRELL, physician to the Brompton Hospital for Diseases of the Chest has joined the Medical Advisory Committee of the Asthma Research Council.

# NINETY-SIXTH ANNUAL MEETING of the British Medical Association, CARDIFF, 1928.

TOWER OF ST. JOHN'S CHURCH  
CARDIFF

THE ninety-sixth Annual Meeting of the British Medical Association will be held in Cardiff next summer under the presidency of Sir Ewen Maclean, M.D., F.R.C.P., Professor of Obstetrics and Gynaecology in the Welsh National School of Medicine, who will deliver his address to the Association on the evening of Tuesday, July 24th. The sectional meetings for scientific and clinical work will be held, as usual, on the three following days, the morning sessions being given up to discussions and the reading of papers, and the afternoons to demonstrations. The Annual Representative Meeting, for the transaction of medico-political business, will begin on the previous Friday, July 20th. The provisional programme for the work of the Scientific Sections is being drawn up by an Arrangements Committee, consisting partly of Cardiff representatives and partly of members appointed by the Council of the Association. The names of the Presidents of Sections are given in a Current Note published in this week's SUPPLEMENT, the full list of officers, together with other details of the arrangements for the Annual Meeting, will appear in later issues. On the last day of the meeting (Saturday, July 28th) there will be excursions to places of interest in the neighbourhood. The Association last met at Cardiff in 1885. We publish below the first of a series of historical and descriptive articles on the city and its medical institutions, written for the occasion by Dr. Donald R. Paterson.

## CARDIFF AN INTRODUCTORY NOTE.

CARDIFF suffers in the mind of strangers from two misconceptions. They generally seem to think, first, that it is an entirely modern and even mushroom town, and, secondly, that it is black with coal dust and coal smoke. As a matter of fact, Cardiff is among the oldest towns in the country, and, at all events for a business town, among the cleanest. The coal measures come to an end about five miles north of the city, and with them the disfigurement of town and country that seem inseparable from industrialism. Cardiff, situated on an alluvial plain, ringed with hills, on the shore of the Bristol Channel under the lee of Penarth headland, is singularly free from coal smoke and coal dust. The coal tips, and with them the coal dust, are away at the docks, which are separated (like Athens from the Piræus) from the shopping and residential part of the town by a long and, it must be confessed, an unlovely street, only made interesting by its extremely polyglot shop names and signs. Further, Cardiff does not consume much coal for industrial purposes, and the clean atmosphere which it enjoys permits the Portland stone of its public buildings to weather to a silveriness not often seen.

There are few prettier approaches to the centre of a big town than the approach to Cardiff from the west over the river Taff flowing between public gardens on one bank and Lord Bute's castle and grounds on the other, from its hills to the north and to the south flowing past the recreation ground, with Penarth headland to close the view.

### OLD AND NEW

The town has profited both by its antiquity and by its growth in the last century. (A hundred years ago it numbered some twenty thousand souls who now are between two and three hundred thousand.) By the modernness of its growth it escaped the evils so dangerously aggravated by the industrial revolution, and profited by the sanitary and other reforms thereby forced on the community, and the Minister of Health was able to say only the other day that Cardiff has no real slum.

It has plenty of open spaces, and has planted its thoroughfares with trees. It has Roath Park with its lake to the east, and to the west Victoria Park and the Llandaff Fields leading to the Cathedral. More fortunate still, perhaps, it was able to purchase from Lord Bute Cathays Park, right in the centre of the town, and there to group its public buildings. It is the possession of these buildings, surrounded by parks and gardens that is now perhaps the chief glory of Cardiff. They merit only to attract the attention of all

THE CITY HALL, CARDIFF

interested in the application of architecture to civic need. In its rapid modern rise the city had several times outgrown its buildings, and when the time came to build on a further venture it was fortunate in being able to acquire a park with a fine avenue of trees near the Castle, to be devoted solely to public needs, and in having an enlightened civic authority who not only commended first-rate architects to design the principal buildings, but laid down conditions which established the uniformity, harmony, and proportion of the buildings on the site.

formed such a striking feature of the whole. The buildings already erected in Cathays Park are the City Hall and the Law Courts, the National Museum of Wales, the Glamorgan County Hall, the Technical College, and the University Offices and University College with "in effect," in the words of a high authority, "the most incredibly successful." The frontage to the south with the City Hall occupying the middle, its tall clock tower a magnificent landmark, flanked on the west by the Law Courts on more severe lines, and on the east by the National Museum, justly termed a masterpiece, is an achievement unique in modern municipal architectural design.

But besides the advantages of its modern growth it has the interest and evidence of antiquity. Here the Roman established a fort and kept in communication open with the hinterland and in mediaeval times the Norman made the town the capital and head of his marcher lordship and fostered its trade. The centuries have bequeathed to Cardiff its Castle right in the centre of the town, now the residence of the Marquis of Bute. The

Castle presents in stone an epitome of the history of the town. Retaining the rectangular form which stamps its Roman origin, the reconstructed massive walls combine to show parts of the Roman wall *in situ* as well as Norman work. Within the enceinte may be seen the north gate of the Roman period, and the great Norman castle mound crowned by a ruined stone keep of the thirteenth century. The Castle Lodging or present residence on the west side embodies the fifteenth century and later work enriched with notable additions by the late Marquis and his architect Burgess.

Hard by standing in the heart of the old town is the one survival of Cardiff's old churches the Church of St John the Baptist. Its beautiful tower with a rich coronal of the Somerset Perpendicular style erected in the fifteenth century is a notable landmark. The mother church of Cardiff—old St Mary's—a cruciform structure of the twelfth century which stood on the bank of the Taff was undermined by the river and destroyed. Foundations of churches of the Grey Friars and of the Black Friars have been preserved on the site of the former near Cathays Park, a fragment of a sixteenth century house built out of its remains is still to be seen.

By enlargement of its boundaries Cardiff has recently included the picturesque village of Llandaff and its ancient Cathedral the reputed shrine of St Dyfrig and St Tilio. A stately embodying work of various periods from the twelfth century down the Cathedral with its fine early English west front had long remained roofless, till its skilful restoration half a century ago. The interior decoration is of interest from its association with pre-Raphaelite artists. There are four glass windows by William Morris and the paintings of the panels of the reredos are by Dante Gabriel Rossetti. On the high ground above the Cathedral there is the recently uncovered ruin of a bell tower—an example of the detached campanile—and the ruins of the old Bishop's Palace now form-

ing a gateway to the Palace grounds. Amongst the modern churches there is interesting work of Bodley in the churches of St Gwynn's and St Saviour's, and in addition to the modern secular buildings in Cathays Park should be mentioned the new buildings of the Welsh National School of Medicine—the munificent gift of Sir W. J. Thomas, Bt.

#### EDUCATION, GENERAL AND MEDICAL

In the matter of education Cardiff has made notable progress. Its primary and secondary schools are

almost all modern buildings airy commodious, and equipped with school libraries. A recent addition is an open air school for ailing children. The University College, founded in 1883, after living for a time in wooden sheds is now nobly housed. Most faculties are represented in it. Its medical side has lately been developed into a complete school though the form of its administration has not been finally settled. Technical education has made great strides and the work of its college has undergone rapid extension.

The development of the educational side of the National Museum is a movement in which Cardiff may justly claim to be in the van. The admirably arranged collections in buildings at once elevating and refined are increasingly taken advantage of by children of school age, with the best results. The Cardiff Public Library with its fine collection of Welsh manuscripts and printed books and documents and prints of specially Welsh and Celtic interest is more like a national than a municipal institution.

The medical activities of the city are mainly centred in the

Royal Infirmary. It comprises, on what is now a somewhat crowded site all departments. It is the clinical side of the Welsh National Medical School, and a notable recent addition to it are the fine clinical laboratories of the medical unit erected by the Rockefeller Foundation. At the docks the Royal Hamadryad Seamen's Hospital a modern building which replaced the *Hamadryad* ship looks after the needs of the shipping population. There is a large Poor Law hospital with special departments. The City Mental Hospital is a well equipped institution which has established a wide reputation by its scientific work in psychiatry.

#### COMMERCE AND SPORT

To turn to the commercial life of the city there can be no need to say anything more of the coal industry. Cardiff is the acknowledged coal capital of the world, and its system of docks and industrial appliances is in keeping with its position. Its shipping and ship-repairing industry, with its dry docks are on a comparable scale. The port is probably first in ownership of vessels engaged in the open carrying trade or the world and none suffered more heavily through losses by enemy action in the great war. Cardiff has on its great milling industry and timber trade. In Cardiff the exchanges, Government offices and headquarters of the firms engaged in these industries are at the docks, away from, and

NATIONAL MUSEUM OF WALES, CARDIFF

CARDIFF CASTLE

not in the centre of the town, as in places where big trade developed earlier. Cardiff has always been keen on sport. Its Rugby football club in the palm days was one of the foremost teams in the country. It was the pioneer of the four three-quarters line, and did much to develop the passing game. Its centrally situated ground, in the Cardiff Arms Park on the left bank of the Taff, has been the scene of many memorable contests. Part of the ground is reserved for cricket, where many of the county matches—Glamorgan is a first-class county—we played. The Association football team, though of recent formation, has rapidly come to the front, and is at present holder of the English Cup. Golf clubs around and in the neighbourhood of the city are increasing, and include some links of quite front rank further down the coast.

## CARDIFF'S SETTING

Cardiff is fortunate in its situation. The city is spread out within an amphitheatre open to the Bristol Channel, with scenery of no little variety. On the east, along the estuary of the Severn, the shoreline from the mouth of the Wye to Cardiff is low-lying, and the adjoining district, exposed in places to flooding by the tides, is protected by a sea wall whose history goes back to Roman times. From the Penarth headland to the west the coastline changes to vertical cliffs of lias limestone, which are ever undergoing change. About five miles from Cardiff, where the older carboniferous limestone has resisted the action of the sea, it forms an island at high tide, and between it and the mainland the large and important docks of Barry have been constructed. From there to the mouth of the Ogmore is the shore line of the Vale of Glamorgan, an undulating plateau scored by pleasant little valleys, well wooded, with sheltered villages, many of which contain picturesque remains of a mediaeval castle.

This district, devoted to agriculture, and having in former days "much corn and grass," abounds in evidence of early settlement, and has not a few interesting old churches. North of Cardiff the ground rises gradually to the foothills which form the southern edge of the great coal-field. Five miles from Cardiff the ridge is breached by the gorge of the Taff, the only natural outlet of the coal-field behind it. It was this natural outlet that gave Cardiff its importance as a hundred years ago, when the demand for steam coal led to the development of the mineral wealth of South Wales. Through this outlet the Taff, flowing through the well wooded slopes of the gorge, with the reconstructed fortress of Castell Coch sentinel-like on its eastern shoulder, forms a picture of great charm, and, while it boasts the late Lord Bute's vineyard, suggested a miniature Rhine.

Beyond, the scene is more sombre. The district drained by the upper reaches of the Taff and by its tributaries is the famous steam coal area, upon which depend the existence and prosperity of the city. Its deeply entrenched valleys, at the bottom of which pits have been sunk and a dense urban population has settled, give to the Welsh coal-field a character all its own and explain many of its problems. Above the valleys, bleak and bare hills clothed with rough grass lend interest and variety to the scenery. Then lower fringes, once thickly wooded, still reveal here and there traces of a sylvan beauty that vanished before the needs of an industrial age.

Moreover, Cardiff is particularly well situated for excursions in beautiful neighbourhoods. A glance at the map will show that, with London and Birmingham, the neighbourhood of Cardiff is one of the districts most thickly threaded with railway lines. By these and other means the valley of the Wye and Usk and the beautiful scenery of Monmouthshire and Brecon are easily accessible, and an active service of cross-channel steamers brings North Somerset and Devon and the Exmoor country within the scope of a day's excursion.

One final word. In spite of its modern industrialism, Cardiff has its link not only with antiquity but with romance. Few even of its own citizens seem to remember that it was from Cardiff according to the *Moite d'Arthur*, that Lancelot took ship when he fled from the Arthur whose honour he had betrayed, and from Cardiff also that

Arthur took ship to follow him. It was in what represented Cardiff Castle in Arthur's day that Tennyson's girl But, of course, it was to the citizens of an entirely legendary Cardiff that Tennyson's Geraint said "Ye think the rustic cackle of your bourg The murmur of the world."

## THE BRAIN OF ANATOLE FRANCE

BY  
SIR ARTHUR KEITH, M.D., F.R.S.

ON November 12th, 1924, Anatole France died when half-way through his 81st year. For half a century he had attracted, charmed, irritated, and instructed a vast army of readers recruited from the more intelligent classes of all civilized countries.

Two days after his death his brain, the source of so many deathless pictures, was on its way to the Medical College of Tours, there to undergo detailed examination by anatomists, in the hope that modern skill might detect in its structure some definite basis which would explain the genius of the novelist. The search was conducted by the professor of anatomy, Professor Guillaume-Louis, and his chief assistant, Dr Dubrenil-Chambaudel. After an interval of three years the anatomists have at last drawn up their report, it was read at a meeting of the Academy of Medicine held in Paris last month. From this report we learn that the brain of Anatole France, when stripped of its membranes, weighed only 1,017 grams, some 340 grams—about 25 per cent—less than we expect to find in a man of mediocre ability, that the two cerebral hemispheres, of exactly similar weight, turned the scales at 854 grams—28 per cent below mediocrity. We are told that the fissures and sulci which separated the relatively simple lobes and convolutions of the brain were deep, that the ventricles of the brain were small, and that therefore, in relation to mass, there was an extensive development of cortical grey matter.

No drawing, photograph, or illustration is reproduced to assist the reader in following the dry, descriptive details of the anatomical narrative, but from what we are told and from what can be inferred we must come to the conclusion that there was nothing in the external configuration of the brain of Anatole France which would lead an expert anatomist to infer that it had been the seat of genius. The reporters sum up the results of their examination thus:

"The brain of Anatole France is of an admirable form. It represents a piece of real goldsmith's work, the convolutions being long and sharply delimited, well folded, pressed tightly together, showing a very unusual degree of complexity."

To do them justice one must reproduce their final paragraph in their own tongue:

Pièce d'orfèvrerie, avons-nous dit ce cerveau etait compréhensible pour la qualité à ces déliées petites pendules sorties, sous Louis XV des ateliers de Julien Le Roy l'horloger tournois, et qui, élégantes et légères, sous l'ornement d'un travail de cis l'ure inégalable, portaient un mécanisme d'une précision parfaite.

The reporters may be justified in comparing Anatole France's brain to one of Julien Le Roy's wonderful little clocks, but, before we accept their simile as a possible explanation of the special faculties of Anatole France's brain, let us think for a moment of what we have a right to expect from them. Suppose it was not a brain, but one of these precious little clocks we had asked them to report on. What should we think when, having read their account of its external dimensions, the lettering on the dial, and the exquisite chasing of the frame we find that they have nothing to say of its internal works—that they have not even glanced at them? That is exactly how they have treated Anatole France's brain, they have not sought to determine the extent of any one of the scores or more of its cortical areas, they have not examined the detailed structure of any one of these areas, the vast masses of matter in the basal region of the brain, which must have so much to do with the emotional side of a man's mentality,

are altogether overlooked. My French colleagues may well ask me if I know what an examination of this kind entails—that it means a mastery of the finest neurological technique, a collection of all that is not known concerning the microscopic architecture of the human brain, and three years of hard labour. And I know all these conditions are requisite, and unless they are complied with such a precious opportunity as this has been wasted and their perfunctory labours thrown away.

It is true that there are now many metaphysicians and not a few psychologists who regard the brain as merely a living sponge in which the mind or soul resides and who will be prepared to receive the published account of Anatole France's brain as ample sufficient for all practical purposes. Medical men—anatomists, physiologists, and clinicians—have reason to think differently. Experiments made by design by disease, or by accident have assured them that the brain is a highly organized complex functional structure, and that we yet can hope to discover the exact role played by every collection of its nerve cells and every tract of its nerve fibres and that ultimately the anatomist will be able to assess the potential value of any given brain. It is true that this time has not come, but we have every reason to believe it will come.

Although we know nothing of the finer structural organization of Anatole France's brain, we do know that with it he was performing feats of genius while millions of his fellow countrymen, with brains 25 per cent or even 50 per cent larger, were manifesting the average abilities of daily labourers.

Such an instance may well make our critics sceptical of any direct relationship between mass of brain and manifestations of mental ability. And yet all our speculations regarding man's evolution are based on a close relationship between mass of brain and its capacity to serve man's needs. As we trace the rise of the brain, from the lowest to the highest of living primates, we see that the nearer that any given brain approaches to that of man in mass and in conformation, the nearer does its owner approach to the mentality of man. With the evolution of vertebrate animals we see that mass of brain and complexity of mental reaction have gone hand in hand, but there are notable exceptions. Whales and elephants have the most massive brains and manifest no corresponding increase of ability which can be called mental in any sense. To this old problem I added my little quota thirty three years ago. If we weigh the brains of dogs of graded sizes we find that with each increase in body mass there is an increment in weight of brain this increment decreasing, the heavier the dog. Somehow each additional area or skin and mass of muscle entails an addition to the make-up of the cerebrum, and such additions are not concerned in the manifestation of intelligence. But as Anatole France was a man of average size we cannot ascribe the smallness of his brain to a lack of the 'corporeal concomitant' element though the existence of such an element whatever its fundamental and structural nature may prove to be does explain the massive brain of the whale and of the elephant.

This lack of correspondence between brain mass and mental ability as measured by accepted standards has been a lifelong puzzle to me. I have known in my student days men with the most massive heads and sagacious appearances who proved failures in all the trials to which the world submitted them, and I have known small-headed men succeed brilliantly, just as Anatole France did. What is the solution? Do the conditions of life bring out in a measurable form all the inherent qualities of man's brain? Can we measure them by any system of psychological tests yet devised? Is there not such a quality as depth of feeling which need have no value in any kind of market in the world of commerce, science, art, or literature? What part of the brain is it that makes a man or woman so intensely affected by music by art by suffering or any emotional disturbance whatsoever?

The human brain, one may well believe is an organ that has come to us not only to give the power to understand to judge to remember, to regulate conduct, but also as a purely sensory organ to make us enjoy life

and cling to it. The tests we apply for genius are not those which measure all the powers of which the brain is capable. Many of them are inarticulate or silent. Anatole France, above all, was an intuitionist or human nature who sought, as is the habit of primitive minds for clear and concrete expression. To be an artistic exponent of the wiles of human nature may mean a peculiar ability, but this exceptional power is one we need not be surprised to find associated with a small brain. Such a brain may have limited powers in other directions.

A detailed study of Anatole France's life, so far as it is known, shows us that he was in many senses a primitive man. In the long run I expect it will be found that there is a close correspondence between brain mass and the degree of function subserved by that organ.

## France.

[FROM OUR SPECIAL CORRESPONDENT.]

### SOCIAL ASSURANCE

THE great question of the day which is occupying the thoughts of all members of the medical profession is the law of medical assurance. It has been passed by the Senate, and there is no sort of doubt that it will be passed by the second chamber also. It is fairly certain that it will modify profoundly the conditions of medical practice in France. The matter, serious enough in itself, turns to tragedy when it is realized that the practitioners of medicine have failed to recognize the need for presenting a united front to defend the interests of the French sick. In the last resort there was the only interest at stake. Many of us think that the law will turn the doctors of France into 'functionaries' and are distrustful of anything like a State organization. It may, indeed, be said that the general body of the medical profession as represented by its syndicates is distinctly opposed to the way in which the social assurance law is to be worked. Unfortunately the syndicates have not found a common ground for action, and the ditch dugged between the Union Nationale and the Federation Nationale still yawns. The great efforts that are being made by the wiser heads render it possible to hope that unity may yet be achieved. If they succeed it will be possible to launch this much-talked-of law in a floatable condition, if they fail we seem to be in for a great disillusionment.

### CONGRESSES

The session has begun as is customary, with a series of congresses which have been particularly well attended by our foreign confreres. We have had the two national congresses of medicine and of surgery in Paris and each has had its satellite congresses of the several specialties. Reference must be made in particular to the International Congress of Hydrology at Lyons. British medicine was very well represented at it, and it seems to have marked a turning point in the story of this department of practice which has been called natural therapeutics, and is as greatly admired by some as it is despised by others. Never before have its problems been attacked with so much scientific precision, the clinicians refused to be outdone by the chemists the geologists or the physicists, who attended in large numbers. Doctors of the old school seemed, indeed to be a little perturbed to see the field of simple observation invaded from every direction by the laboratory. The members of the International Society of Medical Hydrology, which was cradled in London, invited the 'hydrologues' to meet them in Rome, and the occasion afforded opportunity for one more fine international manifestation. This friendship, which overpasses frontiers will help to console our war generation, and gives us good hope for the future.

### LE FOYER MEDICAL

Thanks to a very happy initiative, we shall be able henceforth to offer the foreign medical man staying in Paris a welcome he will particularly appreciate because it will afford him the privileges and comforts of a professional club. What we have established is not a scientific institution, but a social centre where information of all sorts is

internal secretion which in some respects was the counterpart of pituitary secretion. The lecturer explained in detail the work which had been done by Harrington and himself in the synthesis of thyroxine, and, in particular, referred to the difficulty which had been experienced in the introduction of the four important iodine atoms in the molecule of thyroxine. An important key to the successful production of this substance had been obtained from the knowledge of a simpler iodine substance which apparently discharged in sponges, corals, and other lowly organized animals similar functions to those effected by thyroxine in the higher animals. Reference was also made to other important hormones, such as insulin, which, it had been stated, had been obtained by Abel in a crystalline form. It was not yet, however, certain whether the crystals obtained by Abel were insulin itself or an inert substance on which the hormone was adsorbed. The physiological action of various hormones and their chemical constitution were illustrated by lantern slides.

#### VITAL STATISTICS

The more outstanding features of the vital statistics of Scotland during the third quarter of the year 1927 are a birth rate of 19.0 per 1,000, a marriage rate of 7.4, and a death rate of 11.1. The infantile mortality rate for the quarter was 67 per 1,000 registered deaths. The death rates from all forms of tuberculosis and from tuberculosis of the respiratory system were 91 and 64 per 100,000 respectively, both slightly higher than in the third quarter of last year. The total deaths registered during the quarter numbered 13,639. In the larger burghs, taken individually, the quarterly death rate ranged from 14.7 in Dundee, 11.9 in Glasgow and in Edinburgh, 11.6 in Perth, and 11.4 in Aberdeen, to 8.7 in Dunfermline, 9.5 in Clydebank, and 9.7 in Motherwell and Wishaw and in Kilmarnock, and the infantile mortality rate varied from 107 in Dundee, 87 in Ayr, 86 in Aberdeen, 83 in Greenock, and 82 in Glasgow, to 38 in Dunfermline and in Perth, 42 in Falkirk, and 45 in Motherwell and Wishaw. 652, or 4.8 per cent, of the total deaths were attributed to the principal epidemic diseases, this number representing 17 from enteric fever, 128 from measles, 41 from scarlet fever, 178 from whooping-cough, 86 from diphtheria, and 202 from diarrhoeal diseases among children under 2 years of age. Deaths from diseases and accidents of pregnancy and childbirth numbered 141, which is 6 fewer than in the previous quarter.

#### ABERDEEN UNIVERSITY RECTORIAL ELECTION

The Earl of Butehead, the Unionist candidate, was elected rector of Aberdeen University on November 12th by the narrow majority of nine votes over his Liberal opponent, Sir Archibald Sinclair. Mr. John Masefield, who stood as an independent candidate, was more than a hundred votes behind either of the others.

#### HOSPITAL FOR CRIPPLED CHILDREN

An appeal has just been issued in connexion with a scheme for a hospital for crippled children, with attached clinics, for the south-eastern area of Scotland. The scheme began with the appointment, at a conference in Edinburgh on March 16th, 1926, of a committee of investigation, which collected evidence from members of the medical profession and others possessing special knowledge. A second conference was held on February 25th, 1927, at which this committee recommended that a central hospital for the cure and care of crippled children should be built on the outskirts of Edinburgh, with major clinics to be formed in the more populous cities of the south-eastern counties of Scotland, that minor clinics should be established in the remoter parts of these counties, and that co-operation between the existing hospitals and the new central hospital was essential. The area to be covered by this scheme includes the counties of the Lothians, Peebles, Selkirk, Roxburgh, Berwick and the west in hill of Fife, Kinross, and Clackmannan. The general idea of the scheme is that the central hospital to be built in Edinburgh should contain 75 beds, for which a sum of £75,000 would be required. It is pointed out that after this capital fund has been provided the cost of maintaining necessitous children up to the age of 16 would be completely provided by parliamentary grants and local authorities.

#### CHINESE MEDICINE

Dr. Clayton Grosvenor, in a lecture recently delivered in Edinburgh on medical work in China, said that the scientific pursuit of knowledge had practically stood still in China except where it was influenced by Western teaching. The whole of medicine was thus in the hands of the ignorant, the unscrupulous, and the quack, and medical practice was riddled with charms. Eight out of every ten children died before they were 2 years old. There was less than one mission hospital to every million people, and Western influence could therefore touch only the fringe of the suffering in China. It had long been seen that the proper way of dealing with the problem was to establish medical schools and to train the Chinese themselves in Western medicine. Recent events had necessitated the withdrawal of missionaries, and even of doctors from the hospitals, but this had allowed the Chinese to carry on by themselves in many places. He believed, however, that, communism having now spent itself, the Chinese for the first time had really come to find their own life and destiny.

## Ireland.

#### MEDICAL SERVICES IN THE FREE STATE

THE report read at the annual meeting of the Approved Societies Association of Ireland referred to the final report published by the Committee on Health Insurance and Medical Services. The report, signed by a majority, expressed the view that a comprehensive State medical service would be the ideal solution of the problems submitted for the consideration of the committee, but they were unable to recommend this on account of its cost (estimated at one and a half million pounds a year) and for various other reasons, the nature of which was not stated, but which Dr. Ronlette described as the lack of co-ordination between the administrative departments dealing respectively with local government and with national health insurance. Failing to carry a recommendation for the immediate establishment of a State medical service embracing insured persons and all "poor persons," and also failing to secure the inclusion of dependents in a medical benefit scheme, the majority of the committee finally recommended a limited scheme of medical benefit, applicable to insured persons only, with an increase of 2d in the weekly contribution, to be borne equally by the employer and the employee. The Approved Societies Association had never any doubt as to the probable outcome of the inquiry. The failure to reach an agreement was anticipated when the constitution of the Committee of Inquiry was announced and it was found that approved societies were denied representation. If the Insurance Commission had supported the societies' demand, that it should be representative of all interests affected instead of setting up an interdepartmental scheme, it is probable that an agreed scheme would have emerged of a nature beneficial to the Irish working classes. This association claims to speak for 80 per cent of the insured population, and felt that the time had arrived for a comprehensive reform of the Poor Law medical services. If that could not be achieved it favoured a scheme of medical benefit for insured persons and their dependents, and expressed its willingness, if necessary, to agree to an increase not exceeding 3d in the weekly contribution. It even thought some immediate improvement of the existing conditions of affairs it was prepared to advocate a scheme of medical benefit for insured persons only, at an additional contribution not exceeding 2d a week. The Departmental Committee on Workmen's Compensation has expressed an opinion in favour of the establishment of a contributory scheme of medical benefit under the National Health Insurance Acts in the interests of disabled workmen. The final report favoured the discontinuance of the provisions of the Insurance Act of 1921. This proposal was acceptable to the approved societies. It was anticipated that the effective membership would be reduced by about 20 per cent as a result of the proposal. There was an almost 100 per cent increase in benefit payments in 1926 and 1927, as compared

with 1925, and there was reason to think that many cases were not referring then doubtful cases to the National Health Insurance Commission for examination by the medical referee which was provided free of cost. The report also dealt with the inadequacy of the sanatorium benefit fund, in consequence of which insured persons affected were called upon to pay for treatment according to their means, notwithstanding that they had already contributed under the health scheme for sanatorium benefit.

## Correspondence.

### THE PHYSIOLOGY OF DEFECATION

AND THE RELATIVE FIGURES OF GASTRIC, DUODENAL, AND JEJUNAL ULCER

SIR,—Dr L. J. Picton, in his interesting letter on the physiology of defecation which appeared in the *JOURNAL* of November 26th (p. 1005), erroneously gives me the credit of being the first to observe "mass peristalsis" in the colon. As a matter of fact the movement was discovered by Holzknecht of Vienna, his work was confirmed by Dr A. F. Barclay of Manchester a few months before my earlier observations were made.

The gastro-colic reflex, which Alan Newton of Melbourne and I described in 1913 results in a deep peristaltic wave passing from any point in the colon for several inches towards the pelvic rectal flexure; it rarely, it ever, starts in the caecum, as suggested by Dr Picton, and the simultaneous movements he describes in the proximal and distal colon have, so far as I know, never been observed. Mass peristalsis after each meal results in the greater part of the contents of the intestines accumulating in the pelvic colon by the early morning. Getting up, having a bath, and eating breakfast together result in a wave of contraction passing down the pelvic colon, so that faeces enter the previously empty rectum, the desire to defaecate is now felt, and the defaecation reflex results in the evacuation of all the accumulated faeces. Consequently, under normal conditions, no further accumulation collects in the pelvic colon until the following morning, so that defaecation after every meal, as recommended by the New Health Society, is unphysiological, and its encouragement by irritating food is one of the chief causes of the recent increase in intestinal disorders.

O'Burne in 1833 was the first to point out that the rectum is normally empty except immediately before defaecation, and that the faeces accumulate in the pelvic colon just above the pelvic rectal flexure, which is marked on the inside of the rectum by the first of the folds described three years earlier by Houston who started the erroneous idea that the lower two rectal folds also have the function of supporting the weight of the faeces.

In your account of the discussion of gastric and duodenal ulcer at the Manchester Medical Society (p. 988) Mr A. H. Burgess is reported to have stated that "duodenal ulcer appeared to be much commoner than gastric ulcer in the North of England, whereas in London gastric ulcer was more common than duodenal." I do not know the source of his information but my experience in hospital and in private practice does not agree with it. Dr L. J. Bartford and Dr T. E. Jones have recently analysed the records at New Lodge Clinic this round that since 1921 we have had 125 cases of duodenal ulcer compared with only 33 cases of gastric ulcer, a proportion of nearly 4 to 1. Jejunal ulcers, which are almost always complications of gastro-duodenal perforated for duodenal ulcer account for no more than 22 additional cases or only one short of the gastric ulcers, the hydrochloric acid was present in every instance, generally in excess so that our investigations do not agree with the statement by Mr Burgess from the Mayo Clinic according to which acidity was present in 20 per cent of 103 cases of jejunal ulcer.—I am, etc.,

ARTHUR F. HURST

New Lodge Clinic Windsor Forest Nov. 28th.

### GROWTH IN ITS PATHOLOGICAL RELATIONS

SIR,—Very many years ago, when a final year student, I wrote a thesis, which I never attempted to publish, in which I argued that the problem of cancer should be approached by endeavouring to ascertain why the cells of a multicellular organism, presumably descended from a unicellular organism, should have lost the power of unlimited multiplication possessed by the latter. I suggested that this power was delegated to the sex glands and controlled by an inhibitory secretion of these glands. I had neither time, means, nor opportunity to pursue the idea. A perusal of Dr Archibald Leitch's paper on growth in its pathological relations (November 19th, p. 929) emboldens me to make these additional suggestions.

That cell multiplication is controlled by a hormone system, including the sex glands and others—for example, the thymus.

That cancer may be due to a failure of this inhibitory hormone system, or

That it may be due to a new hormone produced by a senescent sex gland, or

That it is an attempt to produce another sex gland to replace a failing sex gland, or

That it is a hopeless attempt to produce another individual by a variety of parthenogenesis.—I am, etc.,

GORDON WILSON, M.B.

Thurlstone St. Sheffield Nov. 24th.

### RADIUM AND THE "SURGERY OF ACCESS"

SIR.—In your leading article on radium in the treatment of malignant disease (*BRITISH MEDICAL JOURNAL*, November 19th, p. 945) reference is made to the "surgery of access" and its relation to present day results.

A briefer survey of the evolution of radium surgery readily supplies the explanation of the excellence of the results now obtainable as compared with those of earlier days and shows further that the "surgery of access" is a culminating point of a very definite series of steps or periods of progress in the treatment of cancer. In the first period treatment was essentially accomplished from the surface by means of plaques and large containers. This was followed by the second, the period of radium puncture in which was the attempt to procure a homogeneous radiation of the malignant mass. This represented a considerable advance, but still there remained a large number of growths, particularly those deep-seated in which needling or homogeneous radiation was impossible. This led to the "surgery of access," the present period of radium surgery.

The three distinct principles of radium surgery thus evolved are: (1) The opening up of a way to the tumour. (2) The treatment of the tumour itself by radiation. (3) The application of radium to the lymphatic areas draining the tumour. To those of us engaged on this work and who have for some time been endeavouring to awaken interest in the possibilities of these new methods in the treatment of cancer, the note of recognition in your leading article is specially welcome. We would commend to those who have not yet had the opportunity of studying first-hand the radium work of the schools of Paris, Stockholm, and Brussels a visit to the forthcoming International Congress of Radiology at Stockholm next summer where opportunity will be afforded of seeing some of the work, not only of Heyman but of the other pioneers in radium and radium surgery of the great Continental schools to whom no one informed on the history of radium surgery can do other than pay humble homage.—We are, etc.,

ARTHUR B. SMITH,

M.B. FRCSE

SYDNEY M. SMITH,

London W.1 Nov. 21

### TREATMENT OF PROSTATIC ENLARGEMENT

SIR.—After careful perusal of the very able Bradshaw Lecture by Sir Cuthbert Wallace on prostatic enlargement in your issue of November 19th (p. 937) one is left with a feeling of regret that no mention is made of treating the adenomatous prostate or radiotherapy. Reference is made to radiation in carcinoma of the prostate, but not to the simple enlargement in elderly men.

My own experience of this form of treatment has been exclusively in private practice, but the results have been so generally satisfactory that I have no hesitation in recommending it in cases where the amount of residual urine is small, and where examination justifies the opinion that there is a large excess of adenomatous over fibrous tissue. Personally I always use a deep-therapy apparatus, and treat one field through the perineum, giving 90 per cent U.S.D., and two or three suprapubic fields, carefully focusing the central ray on the prostate by Chaul's method. For the perineal application I have devised a high stool with an opening in the seat, so that the patient can be treated in a sitting posture, and so avoid the lithotomy position.

It has been said that x-ray treatment, by causing fibrous adhesions, renders difficult a subsequent operation. One of my patients was an elderly man, who wanted to do everything possible to avoid operation. I gave him two series of treatments, but failed to benefit him, and he had to undergo prostatectomy. The surgeon informed me that the operation was no more difficult than usual, and that there were no adhesions. This is the only one of these patients I have treated who has, as far as I know, been operated upon, and, though I am aware one cannot draw conclusions from a single case, I think I am justified in recommending so simple a treatment being tried before subjecting an elderly man to the shock and discomfort of a severe operation.

It would be most interesting and instructive if a series of suitable cases of prostatic enlargement could be treated by irradiation at some large hospital, and the results noted, and I feel sure that all radiologists will echo Sir Cuthbert Wallace's wish "that someone who has the means would, by his generosity, render possible a more intensive study of the subject"—I am, etc.,

Cheltenham, Nov. 23rd.

#### TREATMENT OF CANCER BY RADIUM

SIR,—In your leader "Treatment of rectal cancer by radium" in the *Journal* of November 19th (p. 945) you infer that the reason for the want of complete unanimity upon the value of radium in cancer of the cervix is that some surgeons have not had or not taken the opportunity of seeing what is being done in London, Manchester, Stockholm, Paris, Brussels, and many other centres.

One of my cases of carcinoma of the cervix was, I believe, the first one to be treated at the Radium Institute in Manchester in 1914, and since that date I have taken the greatest possible interest in the results obtained by radium, but unfortunately have to form my judgement upon the results obtained in this country upon which a judgement can be made. To state that a number of cases are well at the end of one or two years, or that a few are alive after longer periods, without a statement of the number of cases treated, is useless. When statistics are published in this country showing that cases of carcinoma of the cervix treated by radium have a high percentage of non-recurrence after five or ten years as have those treated by Wertheim's hysterectomy, I will most gladly abandon this operation, which until then I feel compelled to advise and perform.—I am, etc.,

Manchester Nov. 23rd

WM FLETCHER SHAW

#### UNIFICATION OF LOCAL HEALTH SERVICES

SIR,—I read with interest the account in the *Journal* (November 19th, p. 924) of the paper read by Dr Macgregor at Edinburgh on the unification of local health services. It is satisfactory to note that in the discussion which followed most of those taking part emphasized the importance of pressing forward with unification. This is a matter which does not concern only, or even chiefly, those members of the medical profession engaged in whole-time or part-time public health work. The activities of the Ministry of Health and local authorities affect all doctors in various ways, a fact which will be more and more realized as time goes on.

My own experience in these matters is based on membership of the Cambridgeshire county council, and various com-

mittees of that authority concerned with health matters—namely, public health and housing, tuberculosis, milk and dairies, Midwives Acts, and maternity and child welfare. In addition I happen to be chairman of the Local Medical and Panel Committee and vice-chairman of the County Insurance Committee.

In taking part in the proceedings of these committees I have often been impressed with the manner in which the work of them all is linked up, they are, in fact, not independent but interdependent bodies, and therefore should not be each a separate statutory committee, but a subcommittee whose duty it should be to report its proceedings to the local health committee of the area.

The policy of the British Medical Association to endeavour to promote the establishment of such local health committees, analogous to the local education authorities, is sound. It is, however, unfortunate, I think, that the term "abolish" has been used in connexion with insurance committees. These could be retained on much the same lines as the present ones, and in each case under a subcommittee of the main health committee. It is agreed that the administrative work of insurance committees generally can compare favourably with that of most local authorities.

With regard to medical representation on the local health committee, there is no doubt that co-optation of some medical men would be permitted, in the same way as persons of special experience are now co-opted on to local education committees. It must be remembered, however, that co-optation on a large scale is not popular with elected members of local authorities, who object to persons who are not responsible to the ratepayers for their actions having too much influence upon their deliberations.

Medical men should not be content to leave the administration of their affairs in the hands of tradesmen, lawyers, farmers, and persons of independent means, but should themselves become members of local authorities as the chosen representatives of the people. Some object on the ground that they are thereby liable to become involved in political issues, but politics play a very small part in the work of local authorities after election, and, in any case, a strong personality and honesty of purpose will frequently triumph over political prejudices. On association should, moreover, as far as possible, see that medical men are not penalized by membership of local authorities.

It will be remembered that the Association played no inconsiderable part in the establishment of the Ministry of Health. It is unfortunate that so many of the functions of the old Local Government Board, not immediately connected with health matters, were taken over by the Ministry of Health, instead of being transferred to other departments of the State. We should continue to press for rectification of this as well as for unification of health services locally, in any scheme of reform of local government that is proposed.

Administratively a county council would possibly be the most convenient in most cases for the scope of a local health committee, but where an important borough is situated within the area it might administer its own health matters, as it does its education affairs.—I am, etc.,

Cottingham Cambs Nov. 21st

ROBERT LILLIS

#### MEDICAL CONFIDENCES

SIR,—My appreciation and gratefulness for the attitude taken by Dr E. Graham Little, M.P., on behalf of the ethical rights of our profession was mingled with amazement because of the advice of the distinguished lawyers of the House to restrict the privilege "to a special case of venereal diseases."

Is it not evident that, if the privilege from disclosure of evidence is thus restricted, in each case that a medical person should lay claim to such a privilege, the fact that the person concerned is suffering from a venereal disease *eo facto* disclosed and the privilege frustrated? In the discretion of the medical man there is no real guarding of the patient's confidences.

The High Court of the Netherlands has decided—

April 1st 1913, "because only thus it can be prevented that the patient or his family should restrain themselves from seeking medical aid for fear of disclosure of their secrets" (that is to say all that the medical man hears, sees or observes in the exercise of his profession, and that by its nature is to be regarded as secret).

This verdict has been provoked by a medical man, who had returned evidence before the judge, was therefore condemned to prison, and had applied to the courts. This a attitude might be recon-venued everywhere—I am, etc.,

Amsterlam Nov 26th

H PINKHOFF, M.D.

Sir—I am not only expressing my own opinion, but also that of many medical men with whom I have discussed the matter, when I say that far too much is being made of what is called "medical privilege." The cases where medical men have to reveal in court confidences reposed in them, or knowledge acquired by them in the course of their professional work, are few and far between.

Honour alone would compel one to keep any confidence sacred, but a great deal too much importance is laid upon one's subscription to the Hippocratic oath. There is little doubt but that this was intended to be a short guide to medical conduct and included a warning against the only too common fault of gossiping, not only about one's own patients but about folks generally whatever in connexion with my professional practice or not in connexion with it. I hear of so in the life of men which ought not to be *spoken of abroad*. I will not divulge, as reckoning that all such should be kept secret." In the *Sponsio Academicæ* of some universities one affirms that "not without grave consideration shall one divulge anything seen or heard regarding one's patients." Many medical men subscribe under the Piousness Oaths Act of 1868 that they will keep silence as to anything which they have seen or heard while visiting the sick which it would be improper to divulge.

Such instruments merely counsel the keeping of confidence, but make no absolute prohibition as to the divulging of information when it is deemed necessary as for example in the furtherance of justice. It is not for the medical witness to determine whether a question is unnecessary or even harmful to others, and to refuse to answer is surely to put oneself on a higher level than the accredited representative of the King, who one is confident will not allow such questions to be put without a sufficient cause.

In many cases however, it is unnecessary that there should be any publicity as the answer can be made in writing and handed to the judge or as has been suggested the case can be heard *in camera* at the discretion of the judge. Doubtless in a few cases hardship might result from a public disclosure but might not far greater injury arise if medical privilege were allowed and no information were forthcoming? In criminal cases the medical evidence may be the sole guide which would lead to a conviction and in cases of divorce, legitimacy etc the suppression of evidence which the medical attendant could alone give might very easily lead to miscarriages of justice.

It is a trite remark that medical men are not expected to act as detectives but it is surely their bounden duty as mere members of the community to inform the public prosecutor of any crime which may come under their cognizance. If this were borne in mind it would not be necessary for enclosures to be sent or notices to appear in the public press calling on medical practitioners to help the police in certain cases. A very eminent judge once said "I am not for professional etiquette or professional rule. There is a rule of life and a consideration that is far higher than these and that is the duty of every citizen of this country—that my right-minded man owes to his neighbour—to prevent the destruction of human life in this world."

It is mainly in connexion with the Venereal Diseases Regulations that the question of medical privilege has lately arisen but when the judge accepts written statements (for example the card of life) or information obtained by conversation with the medical witness in private, then

in my opinion we ought to accept the law as it stands, and not make a demand for privileges which are not extended to others—I am, etc.,

W G MITCHELL ROBERTSON

Bosc. mbe. Hant. Nov. 26th

Sir,—At a meeting of the Bournemouth Division of the British Medical Association, held last evening, in conjunction with the Bournemouth Legal Society, the subject for discussion was, 'Should communications to a medical man be privileged in legal procedure, both civil and criminal?'

The two chief speakers for the Legal Society were Mr E W Marshall Harvey and Mr W F D'Angibau while for the Division Dr E K Le Fleming and Dr G H Morse were chosen. Unfortunately Dr Morse was unable to attend, and at almost the last moment I was asked to take his place. I was not at the Annual Meeting at Edinburgh, but a couple of hours before I had to speak I had sent me the Association's *Handbook* for 1927-28 in which I saw a short synopsis of the attitude of the B.M.A. on this subject.

Dr Le Fleming opened the discussion in a most able and concise manner, but it is far exceeded the time allowed I had to limit my observations to some five minutes, and I therefore feel justified in asking your kind indulgence to put briefly my very definite views on this burning subject.

There can be no question that forty years ago judges and counsel were far more inclined to respect medical secrecy than they are to-day, and I mentioned two cases to prove my contention: one in the Civil Court and one in the Criminal Court, between 1882 and 1887.

The first case was in the Divorce Court, before Mr Justice Hannen. Mr Underwick leading for the petitioner had in good social position. She pleaded as grounds for divorce, adultery and cruelty the latter being syphilis given her by her husband. The doctor who had to give evidence on her behalf was also the medical man of the husband. Before the case came on for trial the husband defied the medical man to state that he had attended him for syphilis and Mr Underwick at the last conference contended he could not ask the doctor any questions as to respondent's health without his permission. With great difficulty and at the last moment the respondent withdrew his objection and the lady obtained her divorce.

In the other case, before Baron Field, a young man was on trial for murder. A week before the date of trial the solicitor for the defence discovered by chance that the mother of the prisoner had been an inmate of a private asylum in a condition of acute mania during her pregnancy and her son (the murderer) was born soon after her discharge. Nothing would induce the father to allow this evidence to be given but the solicitor decided to have the medical superintendent of the private asylum present with the books to prove the admission of this lady and her condition while there in case the father should reverse his decision. At the final conference between the alienists who were giving evidence and the two counsel engaged for the defence, Mr T Bucknill (afterwards Sir Thomas Bucknill Judge of the High Court) and Mr Charles Mathews (afterwards Sir Charles Mathews Public Prosecutor) both decided that the evidence of residence in the asylum of the murderer's mother could not be given unless the father gave his consent. At the very last moment this consent was given and the evidence in court had we all knew much to do with the jury's verdict. Guilty but insane in spite of a strong summation up by the judge against such a verdict.

The attitude of Bench and Bar has greatly changed since those days and Mr Justice McCauley's judgement as to medical privilege has never been appealed against and still holds good. Hence the strong feeling of the medical profession and the urging by them of some alteration in the law regarding medical privilege.

Personally I from my many years' experience cannot see eye-to-eye with the attitude taken up by the British Medical Association on this question. No general law can be laid down. Each case must be decided on its merits and above all medical men must look upon themselves not only as medical men but as citizens with a duty to help justice in our courts of law and to protect society.

Lord Riddell, in a paper read last June before the Medical Society on "Medical secrets," very clearly put it

defendants' advisers have submitted to the plaintiffs a statement which they are prepared to have read in court and which they have undertaken to publish in its issue of the 8th newspaper. In these circumstances my clients, who have never desired to obtain damages in this matter but were solely concerned—and deeply concerned—with the establishment of their integrity and the vindication of their policy, accept the statement which is made in satisfaction of their action. They make, as I am glad to diminish, and they accept the statement. The statement which it is agreed I shall read with your lordship's permission is in these terms:

#### *The Star Disclaimers*

It is a point I pointed out to us that in article published in the *Star* of September 2nd 1926 on the subject of the New Health Society and the retirement of Sir William Arbuthnot Lane (the President of that Society) from membership of the British Medical Association has been construed as imputing improper motives and behaviour to the British Medical Association—particularly that the Association was oppressive upon medical practitioners, and that I as well as myself red that its hostility to the educative methods of the New Health Society arose from a desire to prevent any improvement in the public health because this would involve loss of fees to medical men and that the Association was reticent solely by the desire to benefit the medical profession without any regard whatever to public health or public interest.

We disclaim the intention of making any such imputations and we are fully satisfied that such a conception of the work and outlook of the British Medical Association would be wrong in fact and unjust and we regret any wrong impression which the publication of the article may have created.

As a matter of fact (Mr. Stuart Bryan continued) the British Medical Association has itself been much concerned—and has caused research work to be undertaken—in the prevention of disease. We are glad of course to have this statement and subject to your lordship's approval the action will be discontinued. As to the cost which are a small matter having regard to the gravity of the case each party is content to bear its own.

Mr. Norman Birkett said I appear with my friend Mr. Caven for the defendants. It only remains for me to say that I agree with the statement of the terms of settlement as outlined by Mr. Bryan and that we are glad that the proceedings have terminated in this manner.

His lordship indicated his assent to the discontinuance of the action.

#### PARTICULARS OF DOCTORS' ACCOUNTS

A Divisional Court of the King's Bench Division (consisting of Salter and Talbot JJ.) on November 22nd held that it was sufficient for a general medical practitioner in rendering his account to a patient simply to specify the date and fee charged per visit and not to be compelled to render particulars of the treatment or advice given to the patient at each visit.

The point arose out of an application made *ex parte* by counsel on behalf of Mrs. Dorothy Anstey, the wife of a solicitor living at Maidenhead for leave to appeal from an order of the judge of the Windsor County Court reversing the Registrar's order which required the plaintiffs, Messrs. Moore Moore and Foote, general medical practitioners of Maidenhead to deliver particulars of their accounts showing the treatment or advice given to the plaintiffs at each visit. The defendants had given the date and fee charged per visit.

Counsel said Mrs. Anstey was suffering from a bad mouth caused by a decayed tooth and Dr. Foote, one of the defendant partners, attended her to a dentist where gas was administered. Dr. Foote, however, further advised Mrs. Anstey to undergo a private examination. Counsel had applied for the matter to be tried in the High Court.

Mr. Justice Salter thought that the doctors would agree to that charges of medical misconduct were made.

Counsel said he wished the doctor to say whether he was attending Mrs. Anstey for anything besides a bad mouth for if that was all there would be no need for him to go to her six times.

The Court during the application said that if doctors were called on when sending in their bills to explain the particulars of each visit, they could not carry on business.

## Obituary

### JOHN CARYLE JOHNSTONE, M.D.

Late Medical Superintendent, Roxburgh District Asylum.

Many of the older practitioners in the Border districts of Scotland and his colleagues in his specialty, will have heard with great regret of the sudden death of Dr. J. Caryle Johnstone, for many years the medical superintendent of the Roxburgh District Asylum. He had been paying his annual visit to several of his old friends to whom he appeared to be in particularly good health and spirits but while staying with a medical friend in Edinburgh he succumbed to a sudden and unexpected heart attack. His life is likely to be known by many of those brought professionally into contact with him and by his colleagues and former assistants who were attracted by his kindly disposition and good qualities of head and heart and became firm friends for life. Cultured and widely read, and more than in clinical work he was always ready to place his experience and knowledge at the disposal of anyone who sought his advice and guidance and his memorial is the institution which he lived so long and so well, and which under his able management became a model of what such an institution should be.

He was born at Wolfscroft House, Hoxburgh, Roxburghshire on May 27th 1855 and was educated at private schools in Leith and Dumfries Academy and Glasgow University where he graduated M.B. and Ch.M. with honours in 1877 having gained distinction in most of his medical classes and winning a medal. In 1882 he obtained the degree of M.D. In the same year he was appointed assistant medical officer at the Leith and Kinnaird Asylum and in 1880 he became assistant physician at the Royal Edinburgh Asylum under the late Sir Thomas Clouston to whom he gave some assistance in the preparation of his *Clinical Lectures* for publication. In 1885 he was appointed medical superintendent of the Roxburgh District Asylum at Melrose. During his term of office it was found necessary to add largely to the accommodation. Fresh land was purchased, a new and satisfactory water supply was obtained and electricity installed. Dr. Johnstone was particularly interested in the question of the nursing of the insane and devoted much of his energies to the training of his nursing staff. His partly instrumental in securing the passage of the Act under which service in the Scottish District Asylums became a prisonable. He contributed several papers to the *Journal of Mental Science* and drew up a scheme of practical training for those engaged in mental nursing which was found useful in other institutions. He also took an active part in the doings of the local Division of the British Medical Association representing his Division on the Edinburgh Branch Council was a strenuous advocate of the interests of the profession at the time of the passing of the National Health Insurance Act and was elected by the county council as a medical member of the Roxburgh County Insurance Committee.

Being crippled by rheumatic troubles to render his resignation in March 1917 after a period of treatment at Bournemouth and Droitwich he took up work again in July of the same year as junior assistant physician at Craig House Mental Hospital under Dr. G. M. Robertson and remained there until some months after the armistice. The last few years he spent mostly at Droitwich.

His private interests were chiefly literary and artistic. He is survived by his wife, a daughter or Deputy Surgeon-General Andrew Fleming Bengal Army and a son and daughter the former a member of the Kenya Colonial Medical Service and at present medical officer of health at Nairobi the capital town.

Dr. FRANCIS WILLIAM UNDERHILL, who died at Maidenhead on October 31st aged 83 years, was a student of St. George's Hospital, and obtained the diploma of M.R.C.S. Eng. in 1865 and L.S.A. in 1866. He took the Fellowship of the Royal College of Surgeons, Edinburgh,

in 1884. At St George's he was senior prizeman in anatomy, medicine, surgery, and midwifery, and won other distinctions. He had held the post of demonstrator of anatomy at St George's Hospital School of Medicine, and was for some time prosecutor in the museum of the Royal College of Surgeons. He served for many years as honorary secretary of the St George's Hospital Medical Society. On leaving London he went to practise in Birmingham, and became honorary consulting surgeon to the Mosely Hall Convalescent Home for Children. Dr Underhill retired from active work about twenty years ago, and settled in Maidenhead, where he kept a private home for feeble-minded adults. His quaintly attired figure and old-world courtly manner made him a well known figure in Maidenhead. He took an active interest in the social life of the town, and was for some years connected with the working boys' club as secretary and treasurer. He was a member of the Windsor Division of the Oxford and Reading Branch of the British Medical Association, and a regular attendee at its meetings. On the formation of the new Windsor Division Dr Underhill entered into its activities with enthusiasm, and although over eighty years of age drove long distances to attend committee meetings. His long experience of administration and his encouragement did much to help the newly appointed officers. During his years of active practice in the Midlands he had served for some time as treasurer of the Birmingham Branch. He was a respected senior sidesman in St Luke's Church, Maidenhead, and had been one of the managers of the Church of England schools. His wife died a few months ago, and he is survived by a son and daughter.

Widespread regret has been expressed at the news of the sudden death of Dr JAMES MELVIN, late of Rochdale, on November 3rd, at the age of 66. Dr Melvin received his medical education at Aberdeen, where he graduated M.B., Ch.B. in 1887. After holding an assistantship at Ramsbottom, near Bury, he began practice in 1890 in Rochdale. On his retirement in 1920 the practice was taken over by his nephew, Dr James Melvin, jun. Dr Melvin devoted himself wholeheartedly to work on behalf of the British Medical Association, and was honorary secretary of the Rochdale Division for twenty years, until his death. He was deputy representative for the Division from 1919 to 1924, and a representative from 1925 to 1927. He was also a member of the Lancashire and Cheshire Branch Council from 1925 to 1927, and vice-president of the Branch in 1925. Dr Melvin was a representative of the Rochdale Medical and Panel Committee, and attended the annual panel conference in London shortly before his death. He took a keen interest in the St John Ambulance Brigade, and was one of the leading members of the Trinity Presbyterian Church in Rochdale, and treasurer of the Rochdale Town Mission. He leaves a widow, with whom deep sympathy is felt.

The following well known foreign medical men have recently died: Dr HERRGOTT, formerly professor of obstetrics and gynaecology at the Nancy Faculty of Medicine; Dr FRANZ PENZOLDT, formerly professor of internal medicine at Erlangen, aged 78; and Professor E. ZIMMOW, formerly head of the department of microphotography at the Robert Koch Institute, Berlin, aged 85.

## Universities and Colleges.

### UNIVERSITY OF OXFORD

At a congregation held on November 26th the degree of Doctor of Medicine (M.D.) was conferred on B. C. Scholefield.

### George Herbert Hunt Travelling Fellowship

An examination for a three months fellowship of the annual value of £300, and tenable for two years, will be held during Hilary term 1928 commencing on February 11th at 10 a.m. Candidates who must not have exceeded five years from the time of passing the last examination required for the degree of Bachelor of Medicine, should send their names and qualifications, etc., to the University Museum, on or before February 13th.

### George Herbert Hunt Travelling Scholarship, 1928

This scholarship is awarded without examination every second year to a graduate in medicine of the university (of either sex) who has not exceeded five years from the date of passing the final examination for the degree of Bachelor of Medicine. The next election will be made in April, 1928. Candidates must send their applications to the Dean of the School of Medicine, University Museum, Oxford, from whom full particulars can be obtained, on or before February 14th, 1928.

### UNIVERSITY OF EDINBURGH

THE chair of forensic medicine, vacant by the death of Professor Harvey Littlejohn, has been filled by the appointment of Dr Sydney A. Smith, at present principal medico-legal expert to the Egyptian Government Service and professor of forensic medicine in the Cairo School of Medicine. Dr Sydney Smith is a former Vans Dunlop scholar and Gunning prizeman in the University of Edinburgh, he graduated M.B., Ch.B. with first class honours in 1912, and proceeded M.D., winning the gold medal in 1914. He is the author of a textbook on forensic medicine and in January, 1926, contributed an article to the BRITISH MEDICAL JOURNAL entitled "The identification of firearms and projectiles as illustrated by the case of the murder of Sir Lee Black Pasha." According to a Reuters telegram he will leave Egypt to take up his new duties at the end of March.

### SOCIETY OF APOTHECARIES OF LONDON

THE following candidates have passed in the subjects indicated

SURGERY—D. E. Bowon W. B. Hallums H. T. Ince M. H. Rishwan H. T. Rylands M. L. Tschouschner T. de L. Walker R. W. Wood  
MEDICINE—A. F. J. D. Arey P. F. Fanaken T. M. Joseph I. O. B. Shirley M. E. Tschouschner  
FORENSIC MEDICINE—A. F. J. D. Arey P. F. Fanaken L. W. Sanders M. L. Tschouschner J. L. M. Wood  
MIDWIFERY—J. S. Bury G. N. Fox A. Hamid T. M. Joseph A. K. Rama Chandra M. F. Tschouschner

The diploma of the Society has been granted to Messrs A. I. J. D. Arey, P. F. Fanaken, T. M. Joseph, M. L. Tschouschner, and T. de L. Walker.

## The Services.

### ROYAL AIR FORCE MEDICAL SERVICE

THE annual dinner of the Royal Air Force Medical Service was held at the Connaught Rooms, London, on November 25th, with the Director, Air Vice Marshal David MUNRO, C.B., C.I.E., in the chair. In proposing the health of "The Guests"—for whom Lieut. General Sir MATTHEW LILL, Director General, Army Medical Service, responded—Air Vice Marshal MUNRO made a few prefatory remarks about the present position of the service of which he is the head.

The chief difficulty of the moment, he said, was shortage of personnel, but the causes of this were general to all the medical services and not peculiar to the Royal Air Force. Indeed, so far as the R.A.F.M.S. was concerned, he saw distinct signs of improvement in recruiting. Apart from that, two things had happened which would make any shortage less acutely felt. The first was a change in the proportion of officers serving overseas to those at home due to reduction in Iraq and expansion at home. The second was an increase in the authorized proportion of permanent officers. Both the factors would operate in diminishing the number of moves increasing time spent at home, and giving more opportunities for study leave. In regard to study leave one of the ways in which the R.A.F.M.S. had felt the shortage and frequent changes of personnel had been the difficulty of selecting for training the young permanent officer to replace later on the one engaged in various branches of professional work requiring expert knowledge and experience. Good surgeons, pathologists and physicians were essential in the hospitals and experts were needed in various special branches of medicine. All this in the medical and physiological problems peculiar to aviation. The service already possessed such experts but to maintain the flow of them men must be chosen at an early stage of their career. At the top end of the flow so to speak the war potentials of the higher ranks reserved for promotion for purely professional purposes were opposed to administrative attainments. As for the medical officer stationed on aerodromes often well handled and furnished, the majority of the service although they got practical experience, what might be called the normal practitioner and medical officer of health standards, though he concerned in the day-to-day work among the wives and families of the station and in fact in medicine, their service duties were apt to be monotonous. An endearment as being made to give a more professional opportunity by removing them from the aerodrome but the lighter tasks in such quarters and encouraging them to use these more as cottage hospitals to the aerodrome.

of the year with regard to the medical profession and to the various ways they were trying to help the medical profession.

In the Director's report on the other hand of the last year, it was the opinion of the committee that at Halton which would undoubtedly be the chief centre of the R.A.M.C. The other was the starting at Halton of the medical training department for medical officers and medical staff.

#### THE R.A.M.C. ASSOCIATION

The Royal Army Medical Corps Association was formed in 1925 with the following objects in view: (1) To foster esprit de corps (2) To develop and maintain friendly relations between present and past members (3) To assist in obtaining employment for its members (4) To assist or bring to the notice of the R.A.M.C. Fund Committee or other organization any case of members widows or orphan children or members who may be in necessitous circumstances and deserving of assistance (5) To organize periodical reunions and social functions for the mutual benefit of members in the various districts where branches of the Association are established.

The president is the Director General M.S. and the honorary treasurer is Colonel H. Kraggs C.B. C.M.G. The Association is a whole unit controlled by a central committee with offices at Claverton Street S.W.1 and each branch is managed by a local committee. All ranks of the R.A.M.C. and of the Army Dental Corps including officers, are eligible for membership. An important part of the Association's work consists in helping its members to obtain civil employment and medical practitioners and hospital secretaries requiring men trained in all branches of hospital work—dispenser, clerk, laboratory assistant, porters, caretaker, etc.—are invited to apply to the secretary at the head office.

### Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

THE *Home or Commerce* Bill is making slow progress with the Unemployment Insurance Bill. There is scarcely any hope of sufficient agreement between friends of county council and those of lesser local bodies to justify the Government's attempt to pass the Nursing Homes Bill this year but the opposition to the Mental Deficiency Bill is so numerous and that measure has a better chance of becoming law.

At a meeting of the Parliamentary Medical Committee on November 24th Dr. Graham Little resigned the office of secretary to the committee and Dr. Vernon Davies accepted an invitation to carry on the duties provisionally till the end of the session. The committee discussed the position of the Mental Deficiency Bill and of the Nursing Homes Bill.

#### Smallpox

The number of cases of smallpox notified in England and Wales during recent months was considerably smaller than the number notified in the early months of this year. When the report of the Committee on Vaccination appointed last year was likely to be issued could not yet be stated. The case of a child slaughtered after the production of lymph and a child as healthy as the child of the person who supplied the calf. Those would for good and subject to further examination by officers of local sanitary authorities.

Sir Kingsley Wood has said in reply to a question that the Minister of Health had considered the suggestion that he should discontinue the practice of printing a form of declaration objecting to vaccination on the vaccination form handed to the parent when the birth of a child is registered and should revert to the former practice of simply printing a notification on the vaccination form that if the parent had a conscientious objection to vaccination he could obtain a form of declaration to that effect from the vaccination officer. The Minister of Health however had come to the conclusion that it was not advisable to make any further changes in law or practice until he had had an opportunity of considering the report of the committee presided over by Sir Humphry Rolleston which it was expected would shortly be issued.

Mr. Chamberlain informed Captain MacVean on November 23rd that he had no official information on the cost of the recent outbreak of smallpox in the Easing or Union of the County of Durham. The returns made to his department showed that no person under 15 years of age who had been vaccinated prior to infection contracted smallpox.

*Nursing Homes and Mental Deficiency Bills*—On November 25th Mr. Baldwin replying to Mr. Vernon Davies who asked if he would grant facilities for the end of the session for the Nursing Homes (Regulation) Bill said that he could make no promise in regard to time being given for private bill. The final decision in regard to course depended on the state of business. In a previous reply to Sir Herbert Cuyser Mr. Baldwin said the Government might be able to find time for the Mental Deficiency Bill subject to the state of business.

#### Notes in Brief

One firm in his country has commenced blending tetraethyl lead with petrol for a commercial sale. The Factory Department of the Home Office is satisfied that adequate precautions are being taken for protecting workers concerned in the process.

The total cost of administration of National Health Insurance including the cost of central administration was £2,660,000 or 13½ per cent. of the total expenditure.

Grants collected in England and Wales during the year ended March last amounted to £259,000,000.

Since April 1924 the Exchequer has paid £103,000 towards slum clearances.

On November 5th last 238 per 1,000 of the estimated population of England and Wales were receiving Poor Law relief. This does not include lunatics, criminals and persons in receipt of domiciliary medical relief only.

Forty-two authorities in England and Wales maintain open air schools for delinquent children.

### ROYAL MEDICAL BENEVOLENT FUND

It has been the practice of the Royal Medical Benevolent Fund for many years to present to the annuitants and some of the most necessitous grantees a Christmas gift of 25s. The treasurer now makes an appeal for £370 to keep up this practice. The committee has not in hand any special fund to draw upon to meet this Christmas gift to which the recipients in former years are no doubt looking forward. It is a gracious and kindly act, and we have no doubt that many readers will wish to make the continuance possible. Subscriptions may be sent to the honorary treasurer, Sir Charters Symonds, at the offices of the Fund, 11, Chandos Street, Cavendish Square, London W.1.

At the last meeting of the committee forty-nine cases were considered and £576 voted to forty applicants. The following are notes on some of the cases relieved.

Widow aged 55 of M.R.C.S. who died suddenly this year. Left with two sons and one daughter all of whom are raising. Applicant hopes to have about £100 a year when her husband's estate is settled. Her private income is £40 and she has a residence near £1.30 a year as for help to meet the ordinary expenses up to Christmas.

Widow aged 55 of M.B. who was recently removed to a mental hospital as a free patient. She has two girls and a boy the eldest girl is a boarding school and the youngest is with applicant. They are now living on the amount received from the sale of the practice and the money is nearly exhausted. The Fund was asked to help with the boy's school fees and the applicant hopes to meet her other expenses by receiving interest on redemptors. Voted £10.

Widow aged 55 of M.D. who died in 1913. She has maintained herself by teaching but owing to age and ill health finds it difficult to continue. Her expenses are about £12 a week and her income from the Freeman's £10 per annum and from a mercenary guild £3 per week and £9 in 1927 is monthly his ailments.

Daughter aged 50 of M.D. who died in 1900 was brought up by a stepmother and is leaving school has maintained herself. Now able to get a temporary position. Voted £10 and asked to let the Fund in which it is getting on.

Daughter aged 55 of L.R.C.P. who died in 1878. She is without private means and supported herself since 1907. A relative will be very likely a week or two but she has been living on her savings which are rapidly becoming exhausted. Some friends have given her help temporarily. Voted £5 in four quarters to alleviate.

Widow aged 82 of L.R.C.P. and S.I. who died in 1911. She has maintained herself and daughter since the death of her husband by owing to indigent health is unable to do heavy work and is now only earning 10s a week. The Royal Medical Benevolent Fund has asked her £10.

The Royal Medical Benevolent Fund Guild still receives many applications for clothing especially for coats and skirts for ladies and girls holding secretarial positions and suits for working boys. The Guild appeals for second hand clothes and household articles. The gifts should be sent to the Secretary of the Guild 23 Great Marlborough Street W.1.

### Medical News.

SIR HUMPHRY POLLOCK, Bt. regius professor of physics in the University of Cambridge, will open the Bernard Pion Institute of Pathology at the London Hospital on Tuesday next December 6th at 3 o'clock.

A DISCUSSION on alcohol and alcoholism in relation to problems of nutrition and health will be opened by Professor Hugh Macleod, director of the Medical Clinic St. Thomas's Hospital at a meeting of the Society for the Study of Inebriety at 4 p.m. on January 10th.

A SERIES of six debates in aid of King Edward's Hospital Fund for London will be held at the Central Hall Westminster (small hall). The subject of the first on Wednesday, December 7th at 8 p.m. is 'Why are Shakespeare?' and the speakers are Miss Rebecca West and Mr. Ben Greet. Subsequent debates will take place on January 6th and 20th, February 27th, March 26th and April 12th.

DR. TRAVERS SMITH will lecture for the Fellowship of Medicine on practical hints in medicine at 11 Chandos Street on December 5th at 5 o'clock. This lecture is free to medical practitioners. From December 5th to 17th there will be a

special afternoon course at the Infants Hospital, primarily for medical officers of welfare centres and others interested, visits will be paid to some centres outside the Infants Hospital. Lecture demonstrations are being given daily at the West End Hospital for Nervous Diseases, and will continue until December 17th. Beginning on December 5th and continuing for two weeks, a course will be held at the Blackfriars Skin Hospital, two special clinical demonstrations will be given on December 6th and 13th. The following courses will be held in January: medicine, surgery, and the specialties at the Prince of Wales's General Hospital, diseases of children at the Children's Clinic, cardiology at the National Hospital for Diseases of the Heart (limited to 20), and psychological medicine at the Bethlem Royal Hospital. Further information may be obtained from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W 1.

At the meeting of the Royal Anthropological Institute on December 20th, at 8.30 p.m., Dr A. A. Munnford will give a lantern lecture on body measurements, respiratory tests, and school progress.

THE annual dinner of the staff and past and present students of the Royal Dental Hospital of London was held at the Trocadero on November 26th. Among the guests were Sir John Rose Bradford, P.R.C.P., the Hon. Sir William Goschen (chairman of the hospital), Mr L. G. Block, C.B. (Ministry of Health), and Professor Gilmore (president, British Dental Association). The chairman, Mr J. S. Amore of Hastings, recalled that he had spoken at the annual dinner as far back as 1880, when he responded for the students. What struck him most, looking back over nearly half a century of practice, was the different way in which diseases of the teeth were now regarded as compared with former times, and the manner in which the dental hospitals and schools had risen to the occasion. The dean, Mr H. Stobie, said that at the moment there were 104 students as compared with 135 last year, but the drop was only to be expected, it was consequent upon the abnormal increase of students following the war. On the other hand, the entries for the new term were 23, compared with 14 last year. Negotiations were in progress for amalgamation for teaching purposes with Charing Cross Hospital, to have access to a great general hospital would be obviously an advantage to the students. Sir John Rose Bradford, comparing dentistry with general medicine, said that dental practitioners had one inestimable advantage. Although, like medical men, they had to deal with problems set them by nature, they had a conveniently limited field in which to work. Like medicine, again, dental science was a branch of biology, it afforded opportunities for work in comparative anatomy, physiology, nutrition, and pathology. In another respect dental practitioners had the advantage, for the only part of the human body which received legal protection from unqualified practice was the teeth.

ON November 18th, at the Lyceum Club, London, Dr Bertha Mules gave a lunch party to forty medical women and a few non medical friends, all interested in psychological medicine. In the afternoon a discussion on occupation in the treatment of patients was opened by Dr Elizabeth Casson, chairman of the Committee in Psychological Medicine of the Medical Women's Federation. She described the occupation therapy of America, and spoke of the relationship of the crafts to the ordinary domestic duties of a mental hospital. Dr Jane Walker spoke of lace making, gardening, leatherwork, and many other occupations from the practical point of view. Many interesting and divergent lines were taken by the speakers who followed. After tea Dr Shearer, Parishurst, opened a discussion on the treatment of the uncivilized patient. She was of the opinion that the care of the minds of children, particularly schoolchildren, by doctors with specialized knowledge was as important as the cure of their teeth and tonsils. Again many speakers contributed points from widely differing types of experience.

DR JAMES G. MACASKIE, on his retirement from practice in Birmingham after forty eight years, has been presented by his patients and friends with a combined attache and writing case, together with a cheque and a list of subscribers on vellum, and Mrs. Macaskie with a fitted handbag.

THE seventh conference of the National Medical Association of China will be held in the Peking Union Medical College from January 27th to February 2nd. Further information may be obtained from the secretary, Dr C. E. Lim, at the Peking Union Medical College.

THE Alvarenga Prize for 1927 has been awarded by the College of Physicians of Philadelphia to Dr Emil Bogen of Cincinnati, Ohio for his essay entitled "Drunkennes." The next award of the prize, a monetary sum of \$500, will be made on July 14th, 1928. Essays intended for competition may be upon any subject in medicine and should represent in addition to the knowledge and understanding of the subject

based upon original or library research. Essays must be received by the secretary of the College of Physicians of Philadelphia, 19, South 22nd Street, Philadelphia, Pa., U.S.A., on or before May 1st, 1928.

THE Langley Memorial Prize, which was founded by a friend of the late Dr W. H. Langley, C.M.G., principal medical officer of Southern Nigeria, has been awarded to Dr A. S. Bungess of Accra, Gold Coast, West Africa, for his paper, "The selection of a strain of *Bacillus pastis* for the preparation of vaccine, with special reference to the effect of animal passage on virulence."

DR ALICE BLOOMFIELD has been granted an extension of the William Gibson Research Scholarship of the Royal Society of Medicine for a third year. The next award of the scholarship will therefore be made in June, 1929.

THE awards in connection with the Buckston Browne Prize of the Harveian Society of London for the best essay on "The pathology, diagnosis, and treatment of new growths originating in the walls of the urinary bladder" are as follows: Mr Lionel R. Field, F.R.C.S., £100 and medal, proximo. Accessit Mr M. F. Nicholls, F.R.C.S. £10. The president, Dr E. Le Fevre Payne, assisted by Sir John Thomson Walker and Mr Gilling Ball, acted as assessors. An epitome of the prize essay will be read by Mr L. Field at the meeting of the society on Thursday, December 8th, at 8.30 p.m., at the Town Hall, Paddington. The presentation of the medal and cheques will take place at the annual general meeting, to be held on January 12th at 11, Chandos Street, W 1, at 8.30 p.m.

THE Queen Alexandra Sanatorium Fund, which provides grants to enable tuberculous patients with limited means to receive sanatorium treatment at Davos, has expended approximately £1,475 during the year 1926-27, and the maximum number of grants was made. The new scheme, whereby patients reside in approved houses of their own choice and receive a block grant of 50 francs each week, continued to work satisfactorily during the second winter since its adoption. No grants were made for the summer of 1926 or for later than May, 1927. The honorary secretary of the fund is Mr D. Vesey, 97, Warwick Road, S.W. 5.

PLANS have been approved for the new casualty department of the Royal Sussex County Hospital, Brighton, for which Mr Reinhard Baron has presented a donation of £10,000. The accommodation will include a surgery, a minor operating theatre, a sterilizing room, and waiting rooms.

THE medical congress at Cairo known as the Journées Médicales d'Egypte has been postponed until December 15th, 1928, in view of the fact that the Egyptian Government proposes to commemorate then the foundation of the School of Medicine in Cairo.

THE fourth International Congress of Military Medicine and Pharmaceutics, which was held at Warsaw in 1927, decided that an international bulletin of those subjects should be published monthly in the *Archives Médicales Belges*, commencing next January.

MR JOHN D. ROCKFELLER has offered to the Memorial Hospital of New York five annual donations of 60,000 dollars for the investigation of cancer.

THE International Labour Office has published thirteen more leaflets (Nos. 69-81) dealing with nitrous fumes, hot and humid atmospheres, liquid air, air testing in workrooms, occupational diseases of agricultural labourers, nitrocellulose, slaughter houses, celluloid, the jewellery industry, the manufacture of buttons, poisoning by arsenic, pitch and electric lamps. They may be obtained from the London Correspondent of the International Labour Office, 12, Victoria Street S.W. 1.

THE Food Education Society, 24, Finsbury Street, Westminster, has published in pamphlet form the paper on "The reform of institutional housekeeping: a new career for women," read by the honorary secretary of its Joint Hospital Matrons and Schools Committee at the Hospitals and Institutions Conference in May. Copies post free, 7d. on application.

A FUND for cancer research has been presented to the Yorkshire Council of the British Empire Cancer Campaign by Messrs. Hird and Norman Sutcliffe. The value of the gift is estimated at £3,000, and it is hoped that important results in research will follow the experiments rendered possible in the case of larger animals, such as pigs.

THE Ministry of Health has issued a revised list of approved sanatoriums and other residential institutions for the treatment of tuberculosis in England and Wales. It is published by H. M. Stationery Office, price 2d. net.

PROFESSOR H. LEO has been nominated professor of pharmacology at Bonn and Dr Gösta Forssell professor of medical roentgenology at Stockholm.

PROFESSOR MARCEL LABBE has succeeded the late Professor Gilbert as president of the International Association of Physiotherapy.

An association was formed in Hungary in 1833 by the professors of the medical faculty to promote post graduate study by general practitioners. The instruction was free and during the first fifteen years 1,000 doctors took part in 14 courses. In 1910 the Minister for Public Education appointed a committee of management and from 1911 to 1926 it organized 141 courses for 3,360 practitioners, and published under the title of *Orvosok* a periodical containing post graduate articles up to the present time of fifteen volumes have been published. The courses, which are still free include in annual one lasting a fortnight and dealing with internal medicine, surgery, and other departments courses each of a month in various clinics special courses lasting one week, for tuberculosis, venereal diseases, infant diseases, injuries, and social hygiene and weekly demonstrations. The president is Professor L. de Grósz and the secretary is Professor B. Jahn. The address of the Hungarian Medical Post graduate Committee is Maria utca 39, Budapest VIII.

We have received the second issue of *Archivos de Hygiene*, the official publication of the Brazilian Department of Public Health. It contains seven original articles with summaries in French and English on tuberculosis, yellow fever, alimentary hygiene, leprosy, the hospital problem in Rio de Janeiro, and mortality statistics of cancer in Rio de Janeiro abstracts from current literature and public health intelligence.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to **The Editor British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

**ORIGINAL ARTICLES** and **LETTERS** forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the **BRITISH MEDICAL JOURNAL** must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1 on receipt of proofs.

All communications with reference to **ADVERTISEMENTS** as well as orders for copies of the **JOURNAL** should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBERS** of the British Medical Association and the **BRITISH MEDICAL JOURNAL** are **MUSEUM 961** and **2963** and **2964** (internal exchange four lines).

## QUERIES AND ANSWERS

### WHOLEMEAL BREAD

**DR W. H. MARSHALL** (East Grinstead) writes: With reference to the present attention for wholemeal bread can anyone tell the area in the street how to recognize the genuine article? A label of wholemeal in the loaf or on the packing paper appears to afford no guarantee as to the amount of Vitamin B in the flour before or after baking.

### COLD HANDS

**DR JAMES HOLMES** (Bury) writes: I W. G. (BRITISH MEDICAL JOURNAL November 12th p. 900) will first put on a pair of loosely fitting, kid or other leather gloves and draw on over them a pair of ordinary woollen gloves he will find and a remedy for his trouble. I have followed this plan in cold weather for over forty years and find it much more satisfactory than heated gloves. With a little care he can draw both gloves either on or off as though they were one.

### PAIN IN DISSIMINATED SCLEROSIS

**DR G. A. FLEMING** (Nottingham) writes: I have described by G. P. (October 22nd p. 75) is due as seem possible to muscular cramp. I would suggest the trial of small doses of copper sulphate three times a day for a few days. This often gives prolonged immunity from cramp. Copper sulphate 5 grains dilute sulphuric acid 5 minims and chloroform water to 6 ounces given in tea (possibly do as satisfactory but lately I have used 1/10 grain in each made by Mr. Southall's of Birmingham). The remedy was mentioned in this JOURNAL over thirty years ago and since then I have frequently used it as a rule with satisfactory results.

### ANGIO-NEUROTIC OLDEMA

**DR G. E. M. SCOTT** (Larne, Victoria, Australia) writes in answer to *ANX* (JOURNAL August 20th p. 331) I recently had a case of angio-neurotic oedema under my care and found that 10-grain doses of calcium chloride given three daily produced the best result. This patient in addition to swelling on the limbs suffered enlargement of the soft palate and uvula. He found that a glass of saline (iced water) was the best he had also used glycerine of tumeric and a pint. So far the swelling has not returned but he down the throat. The patient was tested for sensitivity to various food proteins but without result.

## LETTERS, NOTES, ETC.

### ETIOLOGY OF THE COMMON COLD

**DR V. S. CHERRY**, medical director in a large pharmaceutical firm in Washington has informed the American Public Health Association that investigations have led him to conclude that the organisms usually considered as the causative factors in the common cold are only secondary invaders which appear in the later stages. He thinks the primary cause is a factor in the metabolism of too much protein food of excess and pre-existing infectious elsewhere in the body. He believes that colds can be prevented or delayed by retaining an alkaline balance in the body by means of diet and carefully regulated doses of sodium bicarbonate or alkali waters together with small quantities of calcium iodide and iodine. He mentions climatic variations only in so far as they inhibit normal activities, thus too much is eaten and too little exercise is taken in cold weather. He finds that colds occur in his particular industry most often on Mondays and the days following holidays and banquets. He calls this about 25 per cent of all enteric in the factor is due to colds or the other effects. More confirmatory evidence will be required, however, before we can dismiss the prevalent view that colds are primarily the result of exogenous infection rather than of defective metabolism.

### A DISCLAIMER AND AN UNDERTAKING

**DR C. LYON WILKINSON** (S. I. County) writes: Referring to paragraphs which appeared in the lay press a little time ago I wish to say that I regret the appearance of such paragraphs in the lay press to the effect that I had acted as an anaesthetist for an unqualified person. I recognize that it is a public interest and contrary to the ethics of the profession for a registered medical practitioner to act in such a manner. I have not now any connexion of the kind with any unqualified practitioner and I will not in the future in any circumstances act in a similar capacity to any unqualified person or persons.

### CATARACT AND ULTRA VIOLET LIGHT

**DR PERCY HALL** (London W.) writes: The communication upon this subject by Mr. Bishop Harman which appears on page 905 of the JOURNAL of November 19th is in my opinion mistaken, and incorrect, and I feel I should not be permitted to pass unchallenged. Mr. Bishop Harman makes in his remarks several cardinal errors. To begin with the fact: Ultra violet light is injurious to the eye. The naked eye if it is focused on the macula will cause a scotoma or blind spot which may leave permanent damage. The naked eye means nothing, naked qualified. I think that Mr. Harman means that arc light which contains a small proportion of ultra violet light and a very large proportion of intensely luminous rays. I suggest to him that it is these luminous rays which cause the ill effects to which he refers. This confusion which exists so commonly in the mind of medical men when referring to ultra violet light provokes an immense amount of misunderstanding and leads them to form hasty opinions often far from correct.

In practice ultra violet light is rarely if ever used alone but in combination with luminous light. Luminous heat and infra-red rays the proportionous difference, profoundly according to the source. The effects upon a patient of exposure to a given source depend upon the spectrum of emission afforded by the source and by the proportionate amounts of various wave lengths in that emission as well as the total intensity of the source in its different constituents and all upon other factors such as age, skin distance, exposure time and idiosyncrasy of patient. In drug therapy the mode of administration whether oral intravenous or by other means profoundly affects the action of the medicine. The effects upon the action of the action of the drug are given alone in a case of pneumonia or in combination with other remedies. The action of the various alkaloids of opium given separately is vastly different from that of opium itself and has physiological effects of opium differ enormously according to whether the dose is minute or large. Similarly veratrine as a poison and in correct dose would produce fatal results. It is commonly admitted in therapeutic doses with good results. I can safely say that the remedy applied with the greatest significance when it is given in the form of light is the heretofore mentioned.

Exposure of patients to sunlight is no comparable to the exposure of patients to any of the commonest sources of artificial produced ultra violet light. There is no possibility to compare the alpine sunlight with the artificial light. In the case there is a relative absence of heat rays which in the other there

THE BRITISH  
MEDICAL JOURNAL

Abdomen, the pain eventually was more pronounced on the left side and was only relieved by morphine. When the acute symptoms passed off his condition was almost that of collapse, and there was frequent micturition with pain at the neck of the bladder after the act of micturition. He was treated in the left lateral position. This examination followed by a later cystoscopic examination. This examination was performed without general anaesthesia, and for about thirty-six hours the injection of beta eucaine, and for about thirty-six hours subsequently the act of micturition was accompanied by severe pain and passing of blood. All bladder symptoms disappeared within about forty-eight hours, and there was freedom from pain and discomfort for nine days when severe pain in the lower abdomen began again. Great irritability of the bladder followed, with constant desire to micturate, only small quantities of urine were passed, and each act was followed by severe pain lasting only a short time, round the neck of the bladder. This condition continued for two days, when a stone was passed through the urethra. Pain and irritability of the bladder gradually passed off, and there have been no symptoms since.

A SOUTH AFRICAN WINTER TYPHOID

Capetown, which is a small town of about 10,000 inhabitants.

HERMANUS is a small town of 1,000 inhabitants, eighty miles from Cape Town, which is now being developed as a seaside resort. Together with two little villages, Poole's Bay and Mossel River it forms the coast of Hermanus. The attractions of this coast consist in the beauty of the scenery, an extensive beach for sunbathing, twelve square miles of water for boating at the Helder River Lake and above all the fishing, which has earned for Hermanus the name of "The Paradise of the Rook Angler." A pamphlet issued by the South African Publicity (Proprietors), Limited gives pictures of anglers standing beside the 100 lb Kabeljauws they have caught, or the 583 lb of fish landed in one afternoon. There are also descriptions of the monuments of the Marine and Riviera Hotels. Dr Looze who has spent his pamphlet, regards Hermanus as an excellent refuge from the English winter its climate is equable and colds and bronchitis or almost unknown. Amongst the other attractions the pamphlet states that at the Old Yeu's Looze fancy dress ball some of South Africa's most austere citizens can be seen in most wend costumes."

DR E BURKE (Darling Assam) writes In reply to "Major R A M C" (October 1st, p 619) I have used iodine intravenously in many diseases with good results employing the following formula suggested in the *Indian Medical Gazette*, April, 1926 p 206 Iodine (pure) 24 grains potassium iodide 36 grains distilled water 1 oz Dose 1 to 2 cc diluted with 8 cc of distilled water 1 inch cubic continuous of the above solution contains 1 gram of iodine. Injections should be given once or twice weekly. Once a week is usually sufficient. In cases showing marked idiosyncrasy to iodine (which very seldom occurs) the dose is halved. I have had striking results in the treatment of pneumonia, erysipelas, cellulitis, rheumatism, septicaemia, and skin diseases, and also in bad cases of tropical chagadanic ulcers. Iodine given intravenously is said to produce marked leucocytosis, and to act also as a blood disinfectant.

Dr. HILWOOD SMITH (Clchester) writes: It seems a pity that many of our professional brethren fail to express adequately the meaning they intend to convey. There is a glaring instance on page 935 in your issue of November 19th where I find "Laparotomy was performed on July 25th by Mr C E Isaac who, on opening the abdomen" etc. This is a manifest contradiction in terms. Laparotomy, a word imported from America means an incision in the flank. It should be laparotomy, as a flank is  $\alpha\pi\alpha$  not  $\lambda\alpha\pi\alpha\sigma\iota$ . The proper word as used by Pland Sutton and others, should be coeliotomy from  $\kappa\omicron\lambda\iota\alpha$  the belly.

**VACANCIES**  
 Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments in hospitals will be found at pages 74 75 76 77 80 and 81 of our advertisement column, and also is mentioned in our advertisement column, and also is mentioned in our advertisement column.  
 A short summary of vacant posts notified in the advertisement column appears in the Supplement at page 219

"G F" a medical practitioner who has recently suffered from renal calculus sent in account of the course of his case until its termination by pyelotomy of the stone through the urethra. I only symptoms suggested stricture and later appendicitis the stricture symptoms were relieved after operation only some discomfort and tenderness in the lower abdomen which pyelotomy relieved by lithotomy in the lower abdomen which pyelotomy relieved. After a month he had repeated attacks of pain in the lower

## DISCUSSION ON CHRONIC APPENDICITIS

### I—SYMPTOMATOLOGY AND DIAGNOSIS \*

BY

WILFRED TROTTER, M.S. LOND. F.R.C.S.,  
Surgeon, University College Hospital

#### THE HISTORICAL POSITION OF APPENDICITIS

IN this year and in this place it is hardly possible to begin the general consideration of any surgical subject without thinking first of its relation to that universal point of reference the Listerian revolution in surgery. Of all the branches of surgery then practised perhaps that of the abdomen responded less quickly than any to the stimulus of the anti-septic method. Of the new procedures that now became possible and that were so boldly put in practice by Lister few concerned abdominal surgery, and we even find him himself actually discouraging Keith from the application of the anti-septic system to ovariotomy. The last quarter of the nineteenth century was by far the most fruitful period that the art of surgery has ever experienced and it was a period throughout of expansion that was as rapid as it was continuous and oh! During that time surgery had become, to an extent it had never before promised to do, an applied science, the successful practice of which was no longer wholly dependent on the exceptional special aptitude of its practitioners. Nevertheless it is only towards the end of this remarkable period that we find abdominal surgery beginning to take on something of its present form and to show the growth that it has made. The largest branch of the art—abdominal surgery—appeared thus in the aftermath rather than in the primary harvest of Lister's work. In many branches of surgery the saving of wounds from external infection was the only step necessary to allow of immediate and rapid progress in abdominal surgery; this step while equally indispensable was rather in the nature of a beginning than of actual achievement. It brought the surgeon not to a summit but to the foot of the final climb and brought him there strong, well equipped, and confident. As soon as the danger of external infection had been disposed of it was possible for there to begin the accumulation of special physiological and pathological knowledge which is the very substance of abdominal surgery.

It might have been expected that such knowledge would be found through an extension of the small incisions of the abdominal field that had already been made in pre-Listerian days, and that had produced the three classical operations of colotomy, herniotomy, and ovariotomy. These were always risky, and to be used only in times of extreme need; their successes were as little open to rational explanation as their failures, but they did represent a definite though a small and precarious conquest from the chaos of abdominal disease. Yet it was not at all chiefly through the exploitation of them that the great modern province of abdominal surgery has been made. They have been incorporated in it, and have had a great and historic importance, but neither of them proved to be of critical value in surgical evolution.

It was in the middle eighties of the last century that Lister's work began to yield that second and secondary harvest which was in some ways even more valuable than its first. Those years for example saw the beginning of surgical neurology, and they saw what is especially relevant to our purpose here, the emergence of the conception of appendicitis from the study of the mysterious and deadly infections of the right iliac region. Here at last was an idea which could fertilize where Lister had sowed, here was a disease ideally suited for the construction of an abdominal pathology. It illustrated every aspect of an infection of internal origin, it illuminated the mysterious natural immunity of the peritoneum and disclosed its limitations; and it showed in its simplest form the essentials of an intraperitoneal operation on the in time. Its historical position thus gives to the surgery of appendicitis

a peculiar significance and prestige, which it retains in spite of having in the due course of nature ceased in many of its aspects to occupy a leading place in controversy and progress.

#### EVOLUTION OF THE CONCEPTION OF APPENDICITIS

In the early years, appendicitis was known almost exclusively as an acute disease capable of producing the most serious abdominal emergencies, and demanding from the surgeon early and exact diagnosis and prompt and resolute treatment. In the evolution of knowledge in abdominal diseases it gradually became evident, however, that appendicitis has another aspect—that in addition to its power of causing acute and sometimes highly formidable attacks, it is capable of producing slow disabling illnesses, with perhaps even greater frequency. These more chronic manifestations are our exclusive concern here, and I shall try to set out a general statement of what seems to me to be their surgical meaning.

It is interesting to recall the well marked stages in which the surgery of the appendix has been built up. At first appendicitis came into the province of the surgeon in the form of abscesses in the right iliac region, which it was found could be satisfactorily treated by drainage. From these cases there gradually evolved the conception of the acutely inflamed appendix as the primary lesion and the regularization of operations to deal with it. A third phase was the recognition of incomplete spontaneous resolution, of the liability to recurrent attacks and the appearance of the "interval" operation. A fourth phase may be marked off by the conception that the acute attack is no essential part of the disease which may be chronic throughout and with but slight fluctuations in intensity. When it was recognized that the intensity of the local manifestations was not necessarily the sole measure of the significance of the disease it became possible to observe the action of appendicitis in leading to distant symptoms and setting up disease in other organs. We may regard this as a fifth, and so far final phase in the general conception of appendicitis. It is this phase which we have to discuss.

#### The Clinical Method

Research in medicine has gained so much by laboratory experiment and methods of exact measurement that I find it hardly possible to use without apology that most characteristic medical instrument—*inquiry* or a merely clinical kind. This the classical method of medicine has many disadvantages, which are perhaps even too much insisted on at the present day. It is for example, in its very nature inexact and it is sadly dependent on the weaknesses of the human mind. For effective use it demands alert yet patient consideration of large bodies of heterogeneous facts and it demands in the observer a familiarity with the material considered closer than that which would be regarded as adequate in any other branch of natural history.

In dealing with our present problem a return to the old-fashioned clinical method is especially appropriate. It is a subject in which we can confidently assume that every one of us has a very large experience. This body of material is made up to a great extent of elusive symptoms and fine shades of ill health in the estimation or which judgment and intuition are less likely to mislead than methods supposedly more exact and finally all the facts are matters of daily familiarity at the bedside and operating table. In these circumstances we shall do well to look only for broad and general conclusions and to attach to them no undue dogmatic weight.

When we come to close quarters with the problem of chronic appendicitis the first question that presents itself is whether such a disease exists as a primary condition. To answer that question we must consult our experience of the morbid anatomy of the appendix region as found at "interval" operations. The conditions we find seem to me to fall naturally into three groups which are practically distinguishable though not sharply separated from one another.

1. The appendix and its neighbourhood show obvious relics of an acute attack. The residue of the attack may be and usually is, a merely *quiescent*, as I shall here

\* In a preceding paper of a discussion in the Section of Surgery at the Annual Meeting of the British Medical Association at Edinburgh, 1927.

appendix is distended throughout or in part, or when there is encysted pus outside of it, or (b) *obscure*, as shown by obliteration of the appendicular lumen more or less complete, with or without old inflammatory adhesions.

2 The appendix appears to be normal. This is, of course, a state very difficult to define. By it I mean to indicate an appendix not unduly long, not abnormally fixed, of uniform calibre, of normal vascularity, and empty.

3 The appendix and the region of it show no clear residue of an acute attack, but are abnormal in certain definite ways so that a fairly constant picture is seen: (a) The appendix is long, (b) it is abnormally fixed either by its mesentery in its proximal half, or by being tied down to the posterior wall of the cecum so as to leave only the tip free, (c) its calibre is not uniform, but shows a moderate dilatation usually towards the free end, (d) it contains elongated, separate, more or less firm faecal masses and its mucous membrane looks swollen and spongy, (e) the lymphatic glands at the root of the appendix and in the ileo-caecal angle have the subglobular shape and glassy look of a chronic inflammatory enlargement, (f) the cecum is rather large and inert and contains solid faecal material.

This third group of appearances—not always, of course, equally developed in all its features—is one frequently met with, it is commonly associated with symptoms that disappear after the appendix is removed, and as it does not appear to have any very direct relation to acute attacks, it perhaps deserves to be regarded as a primary chronic appendicitis.

#### SYMPTOMATOLOGY

We see, then, that there are two broadly distinguishable pathological states which are met with in the course of the "interim" operation for appendicitis, first, the one we referred to as a primary chronic appendicitis, and secondly, the residuary condition left by an acute attack. Both are undoubtedly capable of producing a large range of symptoms, but since we are concerned only with very general considerations we shall not discuss the question of whether there is any difference between the symptoms caused by the two types. In the following remarks it is assumed that one pathological type is as capable of causing the whole range of chronic symptoms as is the other.

#### The Mechanism of Symptoms

The clinical manifestations that experience shows to be associated with chronic appendicitis are many and complex. We may get a clue to the orderly presentation of them by noting two features in the pathological state that indicate the principal mechanisms at work in the production of symptoms. These features are, first, the evidence of septic absorption shown by enlarged lymphatic glands, and secondly, the evidence of disturbed motor and perhaps secretory function shown by the inability of the appendix to empty itself. As we see them in an operation these very familiar phenomena are, of course, purely local, they probably have, however, a much wider significance in making up the clinical picture of chronic appendicitis.

#### Septic Absorption in Chronic Appendicitis

Clinical observation suggests very definitely that chronic appendicitis can produce a series of effects very much like those that may be produced by a chronically infected tonsil. The likeness between the two series is close, and the most cautious observer can scarcely fail to notice in both the special tendency to lymphatic infections, the occurrence of general toxicemic states, the possibility of distant infective lesions, and the incidence of symptoms in inverse proportion to the patient's age.

It is in childhood and youth that the effects of chronic appendix infections are most seriously shown and it is then that is stated the sequence of events which so often results in chronic ill health, dyspepsia, cholecystitis, and peptic ulceration in the adult.

For some reason or other the frequency and importance of the primary effect of absorption in appendicitis—affection of the lymphatic glands—have not received a great deal of attention. Lymphatic enlargement is common at all

ages, but is especially so in young subjects. It is, in fact, unusual not to find it if it is looked for. Probably it is as common in appendicitis as in tonsillitis. The same series of states is met with—chronic enlargement, acute inflammation, tuberculosis. The last-named is doubtless a good deal less common than in the neck and usually runs a more favourable course. If the occurrence of calcification is to be taken as evidence of tubercle, the latter in a mild, easily recoverable form must be regarded as not uncommon.

There can be little doubt, moreover, that acute lymphadenitis is a frequent event in the chronic appendicitis of children and an important cause of local symptoms.

Of more distant absorption effects two groups are to be recognized—the abdominal and the general. The abdominal effects, as is now well recognized, are conspicuously shown in the upper abdominal organs—a fact which suggests a definite relation to infection by the lymphatic path. They are, of course, peptic ulceration and cholecystitis. I shall say little about this extremely important subject, which is so familiar as one of the recent and most distinguished successes of purely clinical observation. I cannot leave it, however, without making some reference to the closeness of the pathological relation between the appendix and the gall bladder. The frequency of cholecystitis in sequence to appendicitis, especially in young women and even girls, cannot fail to impress the clinician whose attention has once been called to it. Indeed, every case of apparently simple appendicitis must be scrutinized with the most anxious care for evidence as to the state of the gall bladder, for one of the common causes of failure of an appendix operation is the coexistence of chronic cholecystitis, with or without gall stones.

Another effect of the chronically infected appendix that may conveniently be mentioned here is its action as the point of entry to the urinary tract (and probably also to the blood stream) of infections of the colon bacillus type. There can be little doubt of the frequent coexistence of appendicitis and urinary infection, and the suggestion of a causal relation is often strong enough to justify removal of the appendix.

The general absorption effects of a chronic appendicitis are much less definitely established, and we shall do little service to knowledge by setting down a long and unimmaculate series of ill to them. With every effort to keep up a properly sceptical and realistic attitude of mind, I find that my experience leads me to suspect a relation between chronic appendicitis and certain defects of nutrition and growth in children, and in a less definite degree between it and certain so-called toxic infections of the heart, osteo arthritis, and some chronic pustular infections of the skin. It does not seem that these can be regarded as more than matters of strong suspicion which must be left to exact inquiry or larger experience to confirm or explode.

#### Disturbed Function in Chronic Appendicitis

It is evident that the chronically infected appendix has difficulty in emptying itself, and that this—probably combined with some defect in its secretory function—leads to the formation in its lumen of faecal masses of various degrees of consistency up to that of actual concretions. This condition no doubt causes the appendix to become the seat of irregular and excessive muscular spasm. There is much clinical evidence that any such focus of abnormal contractions, and especially the appendix, tends to produce disturbances of muscular function throughout the gastrointestinal tract. It is a familiar fact that in appendicitis either of the two opposite kinds of disturbance of motility of the bowel may be met with, result in constipation, but, on the other hand, not very frequently leading to an undue hurrying of the intestinal contents.

It may perhaps be useful at this point to give a moment's consideration to the normal movements of the colon. It is manifest that the faecal masses and the contents of the bowel are passed along at definite rates, the former in a relatively rapid and continuous stream, the latter in a decidedly slower and probably continuous one. The steadiness of the gastric

probably the best stimulus to the contractions which maintain the fecal stream. Now the smooth and symmetrical passage of gas along the colon must demand a very exactly adjusted succession of contractions and is very easily disturbed by a minor degree of mis-coordination. Thus we see why the complaint of flatulence comes to be the constant of all abdominal symptom and how it we regard the infected appendix as a focus of disturbed motility capable of spreading to the colon we can explain the great frequency in chronic appendicitis of abnormal colonic function and especially of constipation.

The other reason of the gastro-intestinal tract that is especially sensitive to secondary functional disturbance is the stomach. Gastric movements and gastric secretion are notoriously apt to be upset by a reflex mechanism and there can be little doubt that such processes are responsible for the well known gastric complications of appendicitis—gastric pain, nausea, capricious appetite and flaccid dyspepsia.

In actual cases the secondary functional disturbances that accompany chronic appendicitis contribute largely to the symptoms of the disease. Their incidence on the stomach or on the intestine varies a good deal but as a rule in any given case both factors are to be observed to a greater or less degree.

It is probable that the frequency and importance of the secondary consequences of chronic appendicitis are still often ignored. This applies especially to the disease as it occurs in childhood. I am fully convinced by clinical experience that in children a large number of the chronic dyspepsias, the recurrent types of vomiting the conditions that may be called general abdominal delicacy are due to simple chronic appendicitis and can be cured by removing the appendix.

#### DIAGNOSIS

The diagnosis in a case of chronic appendicitis is concerned, on the one hand with determining the existence of the disease itself and on the other hand with deciding the presence or absence of complications, and consequently the scope of the necessary operation.

##### 1. Diagnosis of the Disease Itself

Such comments as I have to make on this aspect of the subject may be grouped in relation to the local symptoms and to the general abdominal symptoms.

(a) *Local symptoms and signs* include right iliac pain, tenderness and increased resistance, and increased tension of the right rectus. In observing the three physical signs in this group care and delicacy are necessary because on the one hand the phenomena are often slight and easily overlooked and on the other because the right iliac fossa is probably a little more sensitive in the normal than is the left. A definite difference in the tension of the two recti is probably the most trustworthy sign. With regard to the palpable resistance in the right iliac fossa, it is to be remembered that this is usually contributed chiefly by an overloaded and possibly thickened caecum—in itself a not insignificant evidence of appendicitis. At the same time resistance there may be due to local enlargement of glands—an important and direct piece of evidence. Such glands if deliberately felt for can frequently be made out, especially in children. There is one small local symptom I should like especially to call attention to and that is a special and not very conspicuous kind of pain. It is a sudden momentary stab in the appendix region in itself very sharp but gone at once. It is of occasional occurrence usually when the patient is walking. This 'needle pain' as it might be called is in my experience extremely characteristic when it has been complained of the appendix has invariably been found to show definite pathological changes.

(b) *General abdominal symptoms* are of almost constant occurrence in chronic appendicitis and should take a definite part in the diagnosis. Indeed it is quite commonly the general abdominal symptoms that make the salient feature of the case and may well distract attention from its true nature. The groups of symptoms of this kind which should arouse interest in the state of the appendix can be fairly well defined. In adults there is the well known flatulent dyspepsia there is the group of symptoms

rather suggestive of peptic ulceration but lacking its most characteristic features and there are the symptoms of irregular motility and secretion in the colon that are apt to be called "colitis." In children we meet with similar forms of flatulent dyspepsia, with recurrent attacks of vomiting or of diarrhoea, with 'bilious attacks,' with an intolerance of certain foods, and either alone or in combination with some of these, persistent or recurrent slight degrees of fever.

##### 2. The Complete Diagnosis

The decision that in a given case there is reasonable cause to suspect a chronic appendicitis can usually be made with a fair degree of confidence. This, however is by no means the end of the diagnostic problem for there remains to decide the possibility of some complication or the primary disease.

Three possibilities in this regard have to be kept in mind. First and perhaps most frequent and important, is that of chronic cholecystitis, secondly, that of peptic ulceration of the stomach or duodenum, and thirdly, in women especially those who have had acute attacks, is that of secondary infection of the Fallopian tube and ovary. It is admittedly a difficult matter to make sure that either of these complications is or is not present in a given case.

One obvious and not illogical solution of this problem is to make a full abdominal exploration in every case where it is decided to remove the appendix. In a certain number of cases this is undoubtedly the proper course and the use of it is imperative. I do not however share the diagnostic pessimism which leads to its being regarded as generally necessary. The operation of exploratory laparotomy is a procedure of the greatest value and importance but there are three aspects of it which we shall do well always to keep in mind. When carried out thoroughly it must be regarded as a considerable operation it is in itself by no means without possible complications and sequelae, and though its powers in the clearing up of diagnostic difficulties are great they are not wholly unlimited. In view of these facts the carrying out in a given case of a full exploratory laparotomy should always be a matter for very sober consideration.

If the easy solution of an exploration in every case is not accepted it is obvious that the need for full and exact diagnosis is greater than ever. When however all such precautions are taken there is reason to suppose that the necessities of the situation are to be met by grouping cases from the point of view of treatment into the three following classes.

1. Cases for removal of the appendix by the most straightforward method. This is a numerous class, largely made up of children and other patients in whom there is no clinical evidence whatever of a complication.

2. Cases in which there is reason to suspect some definite complication, so that, in designing the operation it is necessary to provide for access not only to the appendix but also to the upper abdomen or to the pelvis. This group will include a large number of adults and especially such as have had symptoms for long periods.

3. Cases in which a full exploratory operation is necessary on account of some special ambiguity in the symptoms or of a suspicion of malignant disease. It is plain that a great many of the middle-aged and elderly will necessarily come into this class.

If some such grouping of cases as this is carefully carried out we may entertain a reasonable confidence that while the extent of our interventions is not unduly great, we shall not incur serious risk or leaving important conditions unremedied.

It is to be feared that the foregoing remarks have failed to do play appendicitis as an inspiring subject for serious discussion. It is a subject nevertheless which however defectively set forth, must always possess two high kinds of distinction. The biologic nature of appendicitis in the evolution of abdominal surgery is one of these. The other is the fact that the diseased appendix is the first stage in a long series of pathological events and thus affords the surgeon an opportunity for that ideal treatment in which there is a beneficent proportion between the good he does and the trivial intervention by which he brings it about.

## II—DIAGNOSTIC DIFFICULTIES IN CHRONIC APPENDICITIS

J W DOWDEN, F R C S Ed.,  
Consulting Surgeon, Royal Infirmary, Edinburgh

WHEN there is evidence of acute inflammation of the appendix or the patient says there has been an attack of appendicitis a careful history of that attack should be prepared, avoiding all leading questions, and with the endeavour to disclose the following symptoms in order of occurrence: first, colicky pains across the abdomen, or pain about the umbilicus, secondly, the sequel of nausea or vomiting, and thirdly, pain settling in the right iliac fossa with tenderness.

In such cases the diagnosis is very much easier, and I shall confine myself, therefore, to those who have symptoms of abdominal trouble of a chronic character.

In children and the young a chronic appendix lesion should always be suspected when there is a history of listlessness, capricious appetite, colicky pains at times, with perhaps nausea or vomiting. There is sometimes a dread of playing rough games on account of injury to the abdomen, and occasionally it is found that the child cannot bear anything firm round the abdomen, such as a belt. If there is tenderness on palpation over Munro's point the diagnosis is practically complete. There is present at times a small area of tenderness a little below and to the left of the umbilicus, and occasionally also over the pylorus. If pressure is kept up over Munro's point and at the same time applied over each of these other two tender points it is often found that the tenderness at these two points is abolished or greatly lessened.

Tuberculous glands are not uncommon in the right iliac fossa, and may produce local pain and discomfort. There is not the same digestive disorder, and the tenderness is nearer the middle line and more diffuse. It is always well to examine the tonsillar lymphatic glands, which, when they show enlargement, at once suggest the probability of tubercle.

It is necessary to beware of the cyclic vomiting of acidosis. A medical practitioner may see the child several hours after the onset of vomiting and find a tender area in the right iliac fossa due to overaction of the muscles in the course of frequent vomiting. The history of excessive vomiting and the onset without previous abdominal pain should arouse suspicion.

In adults there is a method of examination which sometimes is of value and might be called flat palpation. A flat disc of metal or a small book about four inches in diameter is laid over the area of the abdomen where pain and tenderness are felt. This is pressed firmly down and the patient is asked to put a finger on the disc at the spot where the pain is greatest.

In the adult there are certain conditions of the abdominal wall which may give rise to difficulty. First neuralgic spots may occur, similar to those in intercostal neuralgia. These spots are nearer the middle line; they are often bilateral, and on palpation of the terminal ends of the intercostal nerves there may be found there as well. Secondly, there is occasionally found a condition of incipient inguinal hernia which gives rise to pain and tenderness, but this pain and tenderness is situated over the internal abdominal ring. A good test for this possibility is to apply a small turkey sponge and a speculum of crepe bandage before getting out of bed, if the day passes in comfort the diagnosis is clear. I mention this because I have operated several times on such patients and found a size only about one inch long, though cure resulted from the operation. One patient had had his appendix removed and three subsequent operations for adhesions. Thirdly, there is a rare condition which might possibly give rise to difficulty and that is strain or slight rupture of fibres of the rectus muscle with resultant pain and tenderness. In this case there is, however, a sudden onset during some act of straining. The pain is superficial and over the outer border of the rectus.

Visceritis which usually occurs in women, is as-oc-

cured very frequently with pain in the right iliac fossa. The history will include a gradual onset, constipation and signs such as the narrow intercostal angle and general configuration. On palpation there is often gurgling in the cecum, a more diffuse tenderness, and, if the right kidney is palpable, the diagnosis is facilitated. When, in addition, it is stated that benefit always results from lying down and relief is obtained from a low abdominal support, visceritis is certainly the first thing to be treated.

When there is any suspicion of gynaecological trouble I obtain the assistance of a gynaecologist.

In men, and more rarely in women, duodenal ulcer may be very closely simulated by chronic appendix trouble. There is a history of pain at the pylorus commencing an hour or so after a meal and relieved by taking food, potatoes are often mentioned as an article of diet that is shunned. The patients will add that they are quite well for a day or two or longer, and then suffer pain for a few days, which is markedly irregular compared with the periodic long duration of ulcer pain.

Occasionally there is a reference to pain which radiates at times to the right iliac fossa. On examination pain is present on pressure over the pylorus and also over the appendix. If pressure over the appendix is continued while the pyloric region is palpated, it will be found that in a short time even the pyloric pain disappears or is greatly alleviated. This is a most helpful sign in the diagnosis of chronic appendix trouble.

That chronic gastric disturbance is common with chronic appendicitis is proved by those patients who terminate in a severe attack, and, having had their appendix removed, report that their gastric trouble has disappeared also.

Tuberculous glands in the ileo cecal angle, either sub acute or calcified, may cause local pain, but the tenderness is never the middle line and is more diffuse, there may be other evidence of tuberculous disease. Early tuberculosis of the cecum may closely simulate the chronic appendix, but the frequency of colicky pains without nausea is suggestive of obstruction rather than local inflammation.

Renal and metrical affections may also simulate the chronic appendix, be there haematuria or stone. The frequency of micturition, the pain over the metra or kidney, and the examination of the urine will generally prove the diagnosis.

Symptoms of gall-bladder trouble may be most closely simulated when there is an undescended cecum or a long appendix running upwards with the tip lying close to the gall bladder.

Pneumococcal infection of the appendix, and at times of the cecum, must also be mentioned, one of my patients had the whole colon involved. The appendix is thickened and buff coloured, and when the cecum and colon are involved they also show the same characteristics, which are very marked. One patient, an active young man, had undergone a long course of treatment for duodenal ulcer, but at operation his appendix was found to be typical of pneumococcal trouble, and a culture showed the pneumococcus and Friedländer's bacillus.

## III—GYNAECOLOGICAL CONSIDERATIONS IN CHRONIC APPENDICITIS

VICTOR BONNEY, M.S., F.R.C.S.,  
Surgeon to the Chelsea Hospital for Women and Assistant  
Gynaecological Surgeon to the Middlesex Hospital

THE subject of chronic appendicitis is of the greatest interest to gynaecological surgeons because of the anatomical relationship that exists between the appendix and certain of the female pelvic organs. The right ovary and tube lie close to, and in many cases in contact with, the appendix. The right ovarian pelvic ligament, the broad ligament, and the broad ligament of the pelvis are by passing under the appendix. The appendix is intimately related to, and often less blended with the mesentery of the appendix and

attachments of the caecum and ascending colon to the posterior abdominal wall. The result is that it is often difficult to distinguish pain due to chronic appendicitis from that due to some morbid state of the right appendage or to some condition which gives rise to a dragging of the right ovario-pelvic ligament. Appendicular pain may be attributed wrongly to its origin in the plexus ovaricus and conversely pain originating in the pelvic ovaricus may be misinterpreted as arising from the appendix. Of the two mistakes I should say the second was far the commoner. During the years 1923 to 1926 inclusive 5,613 men and 5,577 women were admitted to the medical ward of the Middlesex Hospital—a practically equal number. During that time 216 operations for acute appendicitis were performed on men and 233 on women—a proportion of 10 to 13. In the same period 172 operations for chronic appendicitis were performed on men and 369 on women—a proportion of 10 to 13. The figures are instructive.

Of the gross morbid states of the right appendix which may give pain simulating chronic appendicitis I would specially cite chronic salpingitis and ovarian blood cysts otherwise known as endometrial cysts or chocolate cysts. Many cases of right-sided pain are diagnosed as due to chronic salpingitis. In this connection we may divide cases of chronic salpingitis into two classes: (1) those where the definite swelling is produced owing to distension of the tube with pus or watery fluid or to gross thickening of the wall of the tube or to associated tubal infection and perforation of the ovary; (2) those in which the tube is merely closed and adherent but without any material thickening or distension. My experience is that it is only the first of these two classes which is commonly accompanied by pain; tubes merely adherent and closed do then enter and do not give rise to pain and are often found accidentally in the course of operations for other disease without there having been any previous indication of their presence. This kind of right-sided pain not associated with a definite swelling or thickening in the region of the appendix is almost surely not due to chronic salpingitis.

A diseased appendix may be adherent to the right tube or the right ovary or to both; in some cases these organs are also diseased either by secondary infection from the appendix or an inflammation chronic in them before the appendix itself became inflamed. Accurate diagnosis in such cases is impossible nor does it matter, so long as the right treatment is recognized—namely to operate on the patient.

The other condition to which I would specially draw attention—namely ovarian blood cysts—is very important first, because it seems to be one of the morbid states the frequency of which is apparently increasing, and secondly because these cysts give rise to pain which in certain respects is very like that due to appendicitis. I may remind you that these cysts are nowadays held to be due to the ovary containing within its substance islands of tissue histologically similar to endometrium. These islands are formed of a cellular stroma with glands embedded in it, like those seen in a section of corpus endometrium; moreover they exhibit the haemorrhages, interstices and interglandular, such as are found in menstruating endometrium. How these endometrial islands come to be embedded in the ovary is too controversial a subject to enter into now nor does it concern the subject in hand, but this intra-ovarian menstruation produces collections of blood in the substance of the ovary having the same appearance and constitution as the chocolate-coloured fluid which fills the vagina in a case of menorrhagia. Ovarian blood cysts are very palpable by the time they attain any size, for not only is the ovary enlarged and densely adherent but a curious and very typical thickening affects the anterior wall of Douglas's pouch, due to implantation in islands of tissue identical with that found in islands in the ovary. The back of the cervix and the upper part of the vaginal wall with the peritonaeum covering them are in short the subjects of an endometriomatosis. In this phase of the disease no confusion with chronic appendicitis could occur, provided the patient was examined vaginally but it is otherwise in its early stages for then the enlargement of the ovary may be too slight to detect, especially

in stout women with the result that the pain, which comes in at intervals corresponding to successive haemorrhages into the ovarian substance, is very easily mistaken for that due to recurring attacks of appendicitis. In making a diagnosis it should be remembered that the attacks of pain due to this intra-ovarian menstruation nearly always bear a definite relation to the woman's periods either occurring at the actual time or a few days before, whereas in appendicitis no such relationship is observable. Such increment to the cysts is accompanied by a local peritoneal irritation but fever is absent and the patient does not exhibit those signs which suggest a lesion of the bowel to the experienced clinician—namely a dirty tongue, foul breath and nausea.

Of all the gynaecological conditions capable of simulating chronic appendicitis the most important are those which give rise to a dragging of the right ovario-pelvic ligament and of the retroversion of the uterus is far the commonest. It might be thought that once a retroverted uterus must drag on the ligament at both sides, therefore the pain should always be felt on both sides and no doubt it is often thus reported but in a large number of cases it is only or chiefly felt on the right side. This is undoubtedly due to the different anatomical relationships of the two sides and this seems to indicate that pain does not originate so much in the ligament themselves as in the structures that they secondarily pull upon. On the right side it is the crown of the appendix or both which are thus affected. There is a further mechanism which obtains in cases of retroversion to which I would draw attention—namely that when the uterus no longer occupies its normal position an empty area so to speak is created into which the intestine prolapses. Thus on the right side the head of the caecum may come to lie upon the posterior walls of the bladder while on the left side a loop of the pelvic colon may occupy the area position.

I am in complete agreement with Mr. Wilfred Trotter that it is very difficult to define a normal appendix but I am of opinion that in many of the cases in which a woman is operated upon for alleged chronic appendicitis the pain is really due to strain on the attachments of the caecum and appendix either because the prolapsed caecum is hanging on them or the ovario-pelvic ligament is pulling on them. I am led to this conclusion because I see so many cases of right-sided pain in which the appendix has been fruitlessly removed before the patient came to me and in which operative cure of a retroversion or prolapse immediately cured the pain. It may be submitted that, given an unhealthy appendix, traction or drag on the appendix or appendicular adhesions must accentuate the symptoms due to the appendix and this is undoubtedly true but it does not account for the large number of cases in which I have operated for alleged appendicitis and have cured the patient not because the appendix I removed was macroscopically or microscopically unhealthy but because I found and relieved at the same time one or other of the displacements to which I have referred.

It is most important in all cases of suspected chronic appendicitis in women to examine very carefully before the operation the condition and position of the uterus and the parts adjacent to it in order to exclude the possibility of the pain being due to haemorrhous drag. It should be remembered that the pain due to this cause is always markedly accentuated or only occurs when the patient is up and about. Remembering causes it to disappear, or to be much less marked. To estimate properly uterine or vaginal displacement patients should always be examined in the standing posture.

I would emphasize most strongly the necessity of making a middle-line incision for all operations for alleged or suspected chronic appendicitis in women for it is only in this way that the presence or absence of the other causes of right-sided pain to which I have referred can be absolutely ascertained. If this was made the rule we should cease to see this very common class of case where the appendix has been removed through a beautiful little two-inch lateral incision for a pain which was due to gross disease or lesion of the woman's generative organs.

IV.—ETIOLOGY AND SEQUELS OF CHRONIC  
APPENDICITISA J WALTON, MS, FRCS,  
Surgeon, London Hospital

It is difficult to visualize and understand the pathological changes responsible for the clinical condition so often described as "chronic appendicitis." That an acute inflammatory attack may be cut short, and the changes abate with resulting deformity, thus making the appendix more prone to a future attack, is a condition which can be clearly envisaged, but that inflammatory changes may persist for years, being chronic throughout the whole of their course and never progressing to an acute condition, yet having profound effects upon the body as a whole, and especially upon certain other viscera, is a condition almost impossible to accept, and our credulity has to be considerably strained to believe that inflammatory changes of this sort could lead to so much alteration in the lining membrane that considerable absorption could take place and could lead locally to advanced fibrosis, and yet never progress to an abscess formation. Doubt as to the presence of such a condition is increased by the clinical observation that so many such cases have been operated upon, with the removal of a fibrous and distorted appendix, and no improvement of the clinical symptoms has followed. Many, therefore, have come to believe that there is no such condition as a chronic primary appendicitis, and Willys Andrews has formulated the dictum, with which many will agree, that a chronic appendicitis should never be diagnosed unless there has been at least one acute attack.

The two important questions to which considerable attention has been directed, and which I shall alone consider to-day, are (1) Is there a primary chronic appendicitis, and, if so, what are its symptoms? (2) What is the relationship of chronic changes in the appendix to lesions in the upper abdomen?

*Primary Chronic Appendicitis a Doubtful Entity*

In the large number of cases which have been operated upon for chronic pain in the right iliac fossa the chief pathological changes found are a diffuse fibrosis of the appendix with obliteration of the lumen, usually commencing at the tip and steadily progressing downwards, and the presence of peritendicular bands binding the appendix to the caecum or under-surface of the mesentery. It is very doubtful indeed whether these two changes are dependent upon primary inflammatory changes or are not rather evolutionary or degenerative. It has been found by many observers that a large number of appendices removed from patients over middle age are fibrous, although there have been no clinical symptoms indicative of appendicitis. There is also no question but that the greater number of patients who complain of persistent iliac pain are women who are subjects of visceroptosis. It is in just such cases that the caecum is found to be mobile, and there is the presence of membranous bands—the so-called Jackson's membrane, which varies considerably in its extent. In nearly all cases it runs in part over the appendix and binds it down, and may easily be mistaken for inflammatory adhesions. In the past a very large number of such cases were operated upon in the belief that the right-sided pain was due to the presence of such a change, but it has since been widely appreciated that the appendix is not the viscus at fault. Very many young women who are generally the subjects of mild vaginal ptosis complain of pain which is localized in the right iliac fossa, and which persists or recurs for years. Skene<sup>11</sup> has drawn special attention to this condition, although earlier stated that pain commencing in the right iliac fossa had his usual due to chronic

found that only 64 patients had been cured of their symptoms, 36 being uncured. The errors in diagnosis were chiefly dependent upon the presence of a mobile caecum. Williams and Slater<sup>12</sup> produced evidence from another angle, for they found that one-third of all women operated upon for pelvic conditions showed undiagnosed lesions of the appendix, and they therefore express doubt as to whether such a condition as "chronic appendicitis" existed. The chief pathological changes were adhesions, pericaecal folds, and chronic fibrosis, which were considered to be of no clinical significance. Unfortunately the belief in the presence of such a condition has persisted owing to the fact that a large number of patients who have been suffering from vaginal ptosis have been operated upon in the expectation that a gastric ulcer would be found, and the only pathological change discovered within the abdomen was one of these lesions of the appendix. This viscus was removed, and owing to the patient having been insufficiently kept under observation after operation it is believed that the operation had led to a cure. Moreover, there are certain cases of vaginal ptosis, especially those seen in girls or young women, where the symptoms somewhat closely resemble those of true appendicitis. It is the inclusion of these cases of ptosis which has led to the belief that chronic appendicitis is a common condition.

On the other hand, there are cases with symptoms referable to the right iliac fossa or simulating those of a gastric ulcer—the so-called "appendix dyspepsia," due to very definite changes within the appendix, such as pus within the lumen, dense adhesions, or strictures with concretion formation behind them. In my experience, however, all such patients have had at least one acute attack. If there has been more than one attack the symptoms are steadily progressive, so that there is never a history of more than two or three attacks at most.

Careful investigation of these cases will, I believe, always lead to an easy differential diagnosis. Not infrequently a change within the appendix may be diagnosed, when there is in reality a lesion of the renal organs or of the pelvic viscera. In the diagnosis of true inflammation from other intra-abdominal lesions the first importance must be placed upon a past history of at least one acute attack. In such an attack the pain will have been severe at first, generalized over the abdomen, and only later referred to the right iliac fossa. It will have persisted for at least one or two days and generally have had the patient up in bed. The diagnosis will have been strengthened if there has been one attack of vomiting at the commencement of the attack, and if the temperature has been slightly raised. If there has been more than one attack they will not have been very frequent. At most there will have been three or four, and they will have been getting progressively worse. In vaginal ptosis, on the other hand, there will often have been a history of thirty or forty attacks persisting over several years. Some of these may have been momentary and the others have lasted only for an hour or so, but rarely are they sufficiently severe to make the patient lie up.

The pain will generally have been intense at first, diffused over the abdomen, and only later localized to the right iliac fossa. It will not have been increased by exercise, nor will it be relieved by lying down, being in those points very clearly distinguished from the pain of caecal dilatation.

In my experience the nature of the hyperaesthesia is one of the most important of physical signs, and its nature being so often misunderstood it has led to more errors of diagnosis than any other point in the history or the physical signs. The area of hyperaesthesia which is found with distension of the appendix is a relatively narrow band running along the groin from the anterior superior spine to the spine of the pubes, being 1½ in. wide and being bisected by Poupart's ligament. This band is clearly seen in cases of acute appendicitis within the first twelve hours. The hyperaesthesia is a dilated caecum found with a vaginal ptosis and lies at the right of and below the umbilicus and lies at the position of the appendix. It is very variable, and even forms a band running half-way round the abdomen but never extends below Poupart's ligament. I

denied that if a patient with pain in the right iliac fossa has an area of hyperæsthesia extending higher than the level of the anterior superior spine, it is most certainly not due to distension of the appendix.

Another very important point is the relation of the physical signs to the time of the onset of the symptoms. In some cases of dilatation of the cæcum the pain may persist for four or five days but there is no progression in the physical signs. If a patient has had an attack of acute appendicitis for this length of time there is certain to be either a perforation or a tumour due to a localized abscess or to dense inflammatory adhesions. Hence if at the end of five or six days the symptoms persist but there is no lump to be felt or no definite rigidity, it is unlikely that the appendix is the fault.

We may say therefore that there is no doubt as to the presence of such a condition as chronic appendicitis but it is much rarer than is usually supposed and is always the end result of an acute attack. I have personally operated upon 932 cases of appendicitis. Of these acute lesions were present in 622 the appendix either continuing pus or showing acute inflammatory changes passing on to perforation or gangrene. The remainder 360 in number had in practically every case a past history of at least one typical acute attack. Only 11 of them have been classified as appendix dyspepsia, a condition which in my experience has been characterized by an acute attack which has then been followed by symptoms somewhat closely resembling those of gastric ulcer or gall stones. In my opinion these figures strongly support the view that chronic appendicitis does not exist as a primary disease but only occurs after an acute attack.

#### *Relation of Chronic Appendicitis to Changes in the Upper Abdomen*

That lesions in the upper abdomen and especially those in the stomach and duodenum can occur in association with infection of the appendix is well known. When I was working as registrar at the London Hospital in 1910 there occurred in our wards one or two cases of severe hæmatemesis after operations for acute suppurative appendicitis. I therefore worked out a case of this occurring in the hospital in the three years 1907 to 1909 inclusive. In this series there were 24 patients who died from severe hæmatemesis after operation and of these 13 had acute appendicitis. A similar proportion was found in a series of acute ulcers found accidentally after death but the patients had not had severe hæmatemesis. It is of interest to note, however, that hæmatemesis and acute ulceration may occur in association with sepsis in any part of the body. It is well to lay stress upon this fact lest it be justifiably assumed that the appendix itself is a direct factor in the causation of lesions in the upper abdomen, for it is quite possible that in gastric and appendicular lesions are found together they are due to a similar infection passing down the intestinal tract or it is even more probable that the infection is blood-borne from any septic focus within the body to the mucosa of the stomach.

Evidence of a close relationship between chronic lesions of the appendix and those of the stomach and duodenum has also been produced. Fenwick, investigating the nature and cause of gastric hypersecretion found that of 112 cases of hyperchlorhydria 22 had chronic changes in the appendix. The next step was the work of Laidlaw, Paterson, and Sir Berkeley Moynihan, who pointed out that a chronic lesion of the appendix might sometimes give rise to a group of symptoms closely resembling those of a gastric lesion, and Paterson in a later paper showed that chronic appendicitis could not only simulate a lesion of this sort but might actually coexist with such a condition. He found that in his series of duodenal ulcers there was definite appendicular disease in 66 per cent.

As a result of this work it has become clearly established that there is a condition which can best be described as "appendix dyspepsia," but my own experience has very definitely shown that it is relatively rare. In my own series of 932 cases of appendicitis there were only 11 in which undoubted disease of the appendix sufficiently closely simulated a lesion of the stomach to give rise to a diagnosis of a chronic ulcer. Moreover, in all these cases there had been at

one time or another a definite history of an acute attack such as is found with true cases of chronic appendicitis. The diagnosis was only accepted if there was a distinct inflammatory change within the appendix, such as a localized abscess or infiltration of the mucosa and submucosa. In all of them there was simply a clinical resemblance between the two conditions, and at operation no organic lesion was found in the stomach or duodenum.

The actual relation between chronic inflammatory changes in the appendix and those in the stomach is not so clearly defined and many surgeons would not admit that it is found in so high a proportion of cases as Paterson found. Sir Berkeley Moynihan in 1921 and J. Schoemaker in 1925 have laid stress upon a condition of valvular congestion of the pyloric antrum with pyloric spasm which is sometimes found with inflammatory changes elsewhere. Schoemaker had 45 such cases in 17 of which a partial gastrectomy was performed so that he was able to study the pathological changes. In none of these cases was there any gastric ulceration. In 16 of them the appendix had been removed, but a chronic obliterative appendicitis was found in only 4 of them it being quite normal in the others. In the cases where the appendix was alone removed the symptoms continued and there was, in addition, one case which occurred some years after the appendix had been removed. On the other hand Deaver and Ravden examined the appendices removed from 76 cases of gall-bladder disease and 18 cases of gastric and duodenal ulcer. They found that the appendix was definitely diseased in 90 per cent of the gall-bladder cases and in 61 per cent of the ulcer cases. Brintwaine believed that a diseased appendix might be shown in a stomach by three conditions: (1) pyloric spasm, (2) pyloric congestion and (3) enlargement of glands in the great omentum. By injection methods he was able to show that there was a direct lymphatic path between the appendix and its neighbours up the lymphatic along the mesenteric artery and so to the glands around the pylorus. The few contributory illustrations of many others that have been written claiming to show that there is a very close relationship between these two conditions and as a result many have come to believe that a primary disease in the appendix is an important factor in the causation of gastric and duodenal ulceration and advocated its removal in all cases. Others have even claimed that the failure to perform such a step in an operation for gastric and duodenal ulceration is a very potent factor in the later formation of gastro-jejunal ulceration. The pendulum has to-day swung much too far and it not infrequently happens that patients have been operated upon in the belief that an ulcer was present and no such lesion being found the appendix has been removed, the surgeon stating that the operation had been performed at so early a stage that the ulcer had not yet developed. I have met with a considerable number of such cases where an operation of this sort has been performed and no relief has been gained. The presence of chronic fibrosis or of membrane formation has been accepted as evidence of a chronic lesion in the appendix when the patient has really been suffering from viscerosplenic or some allied condition.

The other fault upon which Sherren so often laid stress is also not uncommon—that an appendix has been operated upon when the patient was really suffering from a duodenal or gastric lesion but these viscera have presumably not been examined and no relief has followed. In these cases the taking of a careful history and the conscientious investigation of the clinical condition should prevent mistakes of this sort for although the symptoms or lesions of the appendix may somewhat resemble those of a gastric ulcer careful inquiry will nearly always lead to a correct diagnosis.

It is, however, of great importance to estimate as far as possible what is the actual relationship between these two conditions and I think that the figures of my own case throw considerable light on this subject. To the date of my last analysis I had performed 1733 operations for lesions of the upper abdomen. Of these 1603 were for chronic ulcers of the stomach and duodenum, 46 for other non-ulcerous gastric diseases of the stomach and duodenum, 204 for cases of carcinoma of the stomach, 401 for lesions of the gall bladder and ducts and 24 for lesions of the pancreas. In all these cases it is my custom to make a sufficiently large

incision to explore the abdomen thoroughly. The appendix is in every case carefully examined, but it is removed only if there is definite evidence of disease. If it is injected, inflamed, markedly thickened, distended, or even contains many concretions, it is taken out, but a mild degree of fibrosis or the presence of membranes and filamentous bands is not regarded as sufficient evidence of disease to warrant removal. The appendix was excised in 73 cases, approximately 4 per cent, if it had been definitely inflamed or had been the primary cause of the upper abdominal lesion, there should have been further trouble in a considerable number of cases, yet in my total number of gastric and duodenal ulcers the incidence of gastro-jejunal ulceration was considerably under 2 per cent, or, taking only the cases of pyloric and duodenal ulcer, which may be regarded as the only group likely to be followed by this complication, the incidence was between 2 and 3 per cent. This rate compares favourably with many of the published statistics, and I think, therefore, it can be accepted that the omission to perform routine appendicectomy does not in any way increase the possibility of the after-formation of gastro-jejunal ulceration. Of the total of over 1,700 cases only 5 have afterwards developed acute appendicitis. This is an incidence of 0.28 per cent, and is probably but very little, if indeed at all, higher than the incidence in the general population. All these cases have been most carefully watched in a follow-up department, and I feel confident that few, if any, of such complications have been overlooked. These figures show clearly that the relationship between chronic appendicitis and lesions of the upper abdomen is much less intimate than has been believed. The appendix should certainly be examined in every case of such a lesion, but it is only necessary to remove it if there is very definite evidence of disease, and it is never justifiable to inform a patient that the removal of a slightly fibrous or adherent appendix will relieve her of severe abdominal pain.

## DISCUSSION

Mr H N FRETCHER (Brighton) said that if the surgeon followed up his patients who had been operated upon for chronic appendicitis he would find many failures. In 82 cases he had investigated about one-third were failures. In 11 the diagnosis made at the operation was obviously wrong—in 4 cases glands in the mesentery or chocolate cysts in the ovary had been discovered, of the remaining failures the majority were cases of visceroptosis. A history of previous attacks was very important. The symptoms of appendicular dyspepsia were indistinguishable from those due to ulcer of the stomach, and 10 cases of the 82 had been cured by removal of the appendix. These were useful in diagnosis. If the appendix filled well appendicitis was not present, even though there was much delay in emptying. If the appendix did not fill, or filled irregularly, chronic appendicitis was present.

Mr A H BIRCHES (Manchester) thought that tenderness over the right iliac fossa was a good sign of the disease, but there should be comparison of the opposite side by symmetrical pressure. It was very important to have a history of acute attacks. The gridiron incision was only used when the diagnosis of appendicitis was practically certain and only then when the patient was a child. In all other cases he advised thorough abdominal exploration. By following this routine he had discovered an early carcinoma of the colon on six occasions, and early carcinoma of the lower ileum associated with a well marked duodenal ulcer. If the patient was in such a condition that he could not stand this prolonged operation, it was

better, unless the case was urgent, to improve the general health medically and wait until the exploration could justifiably be undertaken. The speaker removed the appendix during the course of this examination, even if it appeared healthy.

Mr ANDREW FULLERTON (Belfast) pleaded for the thorough examination of patients with chronic pain in the right side of the abdomen in whom chronic appendicitis was suspected. He declared that cases of hydronephrosis, cysts of the kidney, even calculus and tumours, might not give rise to any changes in the urine. In doubtful cases specimens of the urine from the two sides should be compared. In cases of calculus, cysts, or tumours the urine secreted from the affected kidney showed a diminished specific gravity. In this way a renal origin for the pain might be discovered.

Mr G H COIT (Aberdeen) referred to the palpation test for chronic appendicitis demonstrated by the late Mr Lockwood. Pressure over McBurney's point elicited a flatulent eripitation which was quite distinct from the large gurgle made by a distended caecum, and was recurrent from minute to minute. He found this test of the greatest possible use, and had only known it wrong three times in a series of 500 cases. When the sign was negative it almost certainly indicated that the appendix was not inflamed, nor were there bands of adhesions. The area of hyperaesthesia described by a previous speaker did not agree with the area he found to indicate that of appendicitis, which was, he stated, triangular in shape, higher, and more to the middle line.

Mr TRYPLE MURFEL (Johannesburg) called attention to Rovsing's sign of pressure in the left iliac fossa, which caused pain in the appendix area, he had found it extremely reliable. In South African natives acute appendicitis was very rare, but chronic appendicitis was not. He did not believe a history of an acute attack was necessary to diagnose chronic appendicitis.

Professor D P D WILKIE (Edinburgh) said that in the past there had been too much operating for chronic appendicitis. Removal of the appendix often failed to cure. The public would submit to operation much more easily than they could be induced to have a complete investigation in order to reach a correct diagnosis. He thought that one of the problems facing the practitioner was to educate the public to seek a thorough investigation. He pleaded for more care before operation. He thought that there were of value for showing an associated lesion in the stomach or duodenum, but for the diagnosis of chronic appendicitis they were useless. However, tenderness in the situation of the appendix under the screen was of some value.

Mr TROTTER, in his reply, agreed with Professor Wilkie, and said that he regarded chronic appendicitis as important because it was frequently the beginning of a train of abdominal disease. Believing this, he thought it was often desirable to perform appendicectomy in children. Tenderness in the right iliac fossa was in 99 per cent of cases of no importance in diagnosis, while visceroptosis might not really be a pathological entity.

## THE ACTION AND USES OF OVARIAN EXTRACTS.

BY

W E DIXON, M.D., F.R.S.

(From the Pharmacological Laboratory, Cambridge.)

The endocrine function of the ovary may now be regarded as established. Knauer showed in 1900 that this organ was intimately connected with oestrus and that ovariectomy could at least partly antagonize the effects of spraying.<sup>1,2</sup> This ovarian action is evident in both sexes. If a portion of an ovary is grafted into a castrated male, the mammary glands and testis hypertrophy, the animal

<sup>1</sup> The opening paper of a discussion in the Section of Therapeutics and Pharmacology at the Annual Meeting of the British Medical Association in Edinburgh, 1927.

secrete, and the animal resembles a pregnant female, a condition obtains which Sturmach calls hyperfeminization. In the male the development of the mammary glands is uninterrupted, the Crithm follicles mature but do not rupture, but the implanted ovaries soon pass into cystic degeneration. In the female the development is slower and shows a rhythm which is apparently associated with the development of the Crithm follicle, and in the regressive phase with its rupture and the formation of the corpus luteum.<sup>2</sup> Loeb has advanced evidence for believing that follicular development is governed by the corpus luteum.<sup>4</sup>

It is also well recognized that the ovary does not function till puberty and that the essential features of puberty are caused by some internal stimulus. A young ovary engrafted into an adult male or female will begin its secretion sooner than its age warrants whilst an adult ovary engrafted into a young animal will not function until the animal reaches maturity. The stimulus to ovarian function can only be obtained through the mature tissues, whether male or female.<sup>5</sup> This fact is of great practical importance since in cases of infantilism it is not necessarily the ovaries which are primarily at fault and ovarian transplantation will not necessarily improve the patient although, as no doubt will be shown in this discussion even in these cases ovarian hormones can produce a sexual cycle.

The literature contains plenty of examples of the beneficial effect of ovarian transplantation both in men and animals. Thus a bitch aged 17 years after an endopertoneal transplantation showed rejuvenation, sexual activity and gave birth to five normal puppies.<sup>6</sup> Bell analyses 118 cases of ovarian grafting and states that menstruation was possible in 107 of these and occurred in 71.<sup>7</sup> Sedukoff<sup>8</sup> transplanted an ovary into a horn of the uterus in two sterile women and obtained normal menstruation.

The present discussion has as its object the determination of how far it is possible to substitute normal ovarian function by ovarian hormones. It should be mentioned here that menstruation is not the same as oestrus, and experiments on lower animals cannot necessarily be referred to man without qualification. Another point to which reference is necessary is the quality of the various extracts at present on the market. Different manufacturing firms make their preparations often by very different methods. The ovary differs from other organs from which extracts are made in that it functions in a cyclic manner. I propose to show that its extract may exhibit different properties according to the stage of the cycle. Manufacturers however so far as I know, take little account of this fact. Again the medical practitioner who uses extracts of ovary administers them in various ways—intravenously, subcutaneously or orally. These two variables must be held responsible for some of the failures and general lack of uniformity in clinical results.

From the ovary at least three different substances can be obtained.

#### Oestrin

Oestrin is the hormone which is most definite and most readily prepared when it is injected subcutaneously into spayed rats and mice it produces typical oestrus with normal sex instincts and when injected into immature animals it induces puberty.<sup>9</sup> Like other hormone, such as adrenaline and thyroxine oestrin is of the same nature in all animals.

The hormone is probably produced by the Graafian follicles at one stage of the ovarian cycle, the concentration in the ovary being least in the post-menstrual period and greatest just before menstruation. It is present in the wall and fluid of the ripe follicles.<sup>10</sup> In pregnancy it is also present in large amounts in the placenta and the blood.<sup>11</sup> In pregnant women it can be detected with certainty in the blood from the eighth to the tenth month. In other women it may also be detected in the blood about fifteen days before the onset of menstruation it increases in amount till menstruation appears when it may be detected in the menstrual blood though not in the circulation.<sup>12</sup>

Oestrin is a thermo-stable liquid soluble in all lipid solvents and also in water under certain conditions, and can be obtained free from cholesterol. The aqueous extracts

lose their power in a few days. It is recognized by physiological tests. Three of the oestrogens have been used: (a) the vaginal smear test, (b) the action in virgin or spayed rabbits causing the uterus, vagina, and mammary glands to hypertrophy, (c) the action on the type of contraction of the isolated uterus. None of these tests is absolutely specific. Thus it is stated that oestritic extracts give a positive result to the vaginal smear test<sup>13</sup> and that the female willow catkins suitably extracted exert a like action on castrated rodents though the effect is said to be more gradual in onset.<sup>14</sup>

An indication of the amount of follicular hormone in a tissue can be made by injections into spayed rodents since this subject is being dealt with fully by Miss Coward it is only necessary to say that the unit is the least amount of lipid extract required to produce a definite effect in the spayed adult rat and that the figure is by no means constant. For clinical purposes the extract should be put up in ampoules each containing 10 rat units per cubic centimetre. By such methods it has been demonstrated that a woman's ripe follicle contains from 5 to 5 units.

Injections of oestrin into spayed animals produce all the characteristics of a heat period. When the concentration of hormone is maintained continually and in sufficient amount a continuous oestrous results.<sup>15</sup> The uterus enlarges and the increase in weight of the virgin rabbit's uterus within a few days of the administration of the hormone forms a qualitative test of activity. This hormone also promotes the building of endometrium. Menstruation is due to the cessation of the influence of this hormone and, therefore to obtain an emmenagogue effect in women the injections should be interrupted at suitable intervals.<sup>16</sup> On the other hand, animals can be kept sterile by continuous injections.<sup>17</sup>

As oestrin exerts this remarkable action it might well be that injections into pregnant animals by bringing on oestrus would cause abortion. Margaret Smith<sup>18</sup> found it was possible to interrupt pregnancy in rats during the first five days by injecting oestrin but that it was not possible after the fifth day. Parkes and Bellerby,<sup>19</sup> in mice, found that even in the later stages injections in sufficient amounts will nearly always terminate pregnancy.

Some observations have also been made on women and monkeys after ovariectomy. Oestrin promoted the growth of the uterus. In monkeys menstruation occurred when the injections ceased in women the subjective symptoms<sup>20</sup> or menstruation only occurred, but no bleeding approximating to that in normal menstruation.<sup>21</sup>

Before leaving this hormone it should be noted that evidence exists for supposing that the production of oestrin is influenced by the anterior lobe of the pituitary gland.

#### Corpus Luteum Hormone

A large mass of experimental observations shows that the corpus luteum is concerned with the rhythm of the oestrous cycle and with the prevention of ovulation. Also it is known that a persistent corpus luteum, both in animals and women, will produce sterility, a condition which is cured by its removal. The presence of fully formed corpora lutea inhibits ovarian secretion and this condition obtains in animals for a time between the heat periods and more particularly during pregnancy. In women there is plenty of pathological evidence to show that functional corpora lutea are not present during menstruation.

If the corpora exert this controlling action on ovarian function, then their removal should release the normal ovarian function. Removal of the corpora in animals, rabbits (Fraenkel) goats (Drummond Robinson) etc., during pregnancy is invariably followed by abortion. On the other hand injections of properly prepared corpus luteum prevent ovulation. Pearl and Surrae<sup>22</sup> found this for the hen. Kennedy for the rabbit. Papanicolaou<sup>23</sup> also finds that corpus luteum inhibits and delays ovulation and oestrus in the guinea pig. One other effect can be induced by these injections—namely hypertrophy of the breasts, and during pregnancy growth of the normal portion of the placenta. Shaw<sup>24</sup> has shown that the corpus luteum is mature in women on the nineteenth day and persists till the twenty-seventh, during menstruation it degenerates. He also thinks that it is responsible for the

production of the premenstrual changes and of the decidua if pregnancy occurs.

Clinically treatment with extracts of corpus luteum has been disappointing, and it is easy to understand the reason. These glands are only functional at one period in their cycle, the degenerated corpus is inactive. Few manufacturers are likely to have assistants sufficiently skilled to make this distinction. Nevertheless remarkable clinical results have been claimed for this form of therapy, and many cases are on record of women who habitually aborted going to full term when treated with corpus luteum extracts.

#### Interstitial Hormone

The third substance which can be prepared from ovarian extract was described by Marshall and myself. This substance is water-soluble and thermo-stable, and can be prepared from the ovary, at one stage of its cycle only, by maceration with warm saline followed by boiling and filtering. The injection of this substance into animals causes a secretion of the posterior lobe of the pituitary gland, and this in turn renders the uterus supersensitive and highly responsive to other forms of stimulation.

The pituitary secretion passes either entirely or mainly into the cerebro-spinal fluid. Histological examination has shown that the gland is suspended in a bath of the fluid and has an opening in communication with the ventricles. Since the experiments of Marshall and myself this secretion of pituitary into the cerebro-spinal fluid has been confirmed many times, more particularly by Trendelenburg,<sup>26</sup> Janisz and Horvith,<sup>27</sup> and Minn.<sup>28</sup> and there can now be little reasonable doubt of this fact. It has been suggested that the secretion of oxytocic substance is not really pituitary, but some other substance, and to this it can only be replied that it exerts every known chemical and physiological action of posterior lobe extracts. In my *Dobson* lectures I gave the last piece of evidence in this respect by showing that it also exerts the melanophore dilator action on the frog, in effect which, so far as I know, is quite specific. Trendelenburg has also described this action.

The pituitary gland must be intimately connected with the phenomenon of pregnancy, because statistics show that the size and weight of the gland in men and nulliparae are about the same. In primiparae the weight has increased by about 50 per cent, and in multiparae by about 90 per cent, though most of this increased weight is due to the anterior lobe.

The posterior pituitary substance has at least three actions of importance in medicine. It inhibits the secretion of urine, it has an antagonistic action to the insulin effect, and it sensitizes and, in large doses, contracts plain muscle on the uterus. This latter action is so profound that it overshadows all the other muscular effects, and pituitary may be said to have a true specific action on uterine muscle in rendering it supersensitive to every form of external stimulus.

Our experiments showed that in only one stage of the ovarian cycle was this hormone elaborated—namely, at the stage of degeneration of the corpora lutea. So long as these corpora are functioning they govern the metabolism of the ovary, and neither the oestrogen nor pituitary hormones are free to act, but when the corpora degenerate both are liberated and exert their effects—that is to say, extracts of the ovary made between the heat periods or during pregnancy are without effect on the pituitary gland, but extracts made just before the heat period or just before parturition induce secretion of the gland. As the significant action of pituitary extract is to sensitize the uterus it is difficult, if not impossible, to avoid the conclusion that these two phenomena are closely associated. It is true that insulin also causes the pituitary to secrete,<sup>29</sup> but this cannot be of importance in these experiments since the blood sugar in anesthetized animals into which ovarian extracts are injected is invariably increased as a result of the anesthetic.

The facts are then that the ovary just before parturition and just before the heat periods contains a hormone which causes the pituitary gland to secrete. It is well known that substances introduced into the cerebro-spinal fluid and then pass almost immediately into the blood, and

hence it should be expected that extracts of blood of pregnant rabbits at the time of delivery should contract the uterus, which has been found to occur. Similarly the blood of women collected at the time of delivery contracts the guinea-pig's uterus to a considerably greater degree than normal blood.<sup>30</sup> The same effect was shown by Meyer in a different way.<sup>31</sup> He collected the cerebro-spinal fluid from women during Cæsarian section. This fluid he injected subsequently into ten women with deficient labour pains. In eight of the women pains were induced, which in four were followed by the birth of the child. In mother also an intradural injection was made, which was followed by labour pains within twenty-four hours. Meyer states that the cerebro-spinal fluid in labour contains the active principle of the pituitary responsible for the production of uterine contraction.

All these experiments consistently support the view that in the presence of fully formed corpora lutea the normal ovarian secretion is held in abeyance, and this is the condition for a short part of the time between the heat periods, but more particularly during pregnancy. In other words, the corpus luteum may be supposed so to dominate ovarian metabolism at these periods that the ovarian secretion, which at other times activates the pituitary, is inhibited or else is neutralized by the secretion coming from the corpus luteum. At the close of pregnancy, when the corpora lutea are in an advanced stage of involution, the normal secretory activity is once more produced, and the pituitary gland is excited to secrete in greater quantity. When the threshold stimulus of the pituitary secretion upon the uterus is reached the pains of labour set in and parturition results. The well known phenomenon of the growing irritability of the uterus in the later stages of pregnancy, which is the typical effect of the pituitary action, is explained as being functionally correlated with the involution of the corpus luteum. In our experiments ovarian extract gave positive results at all times excepting when the organs contained well developed corpora lutea, but the effects produced were undoubtedly more marked in the case of the ovaries obtained at or about the time of labour. The hormone which stimulates the pituitary gland is produced in greatest abundance at these periods.

Rogers also thinks that such a hormone exists, it is stated to be of approved value in such conditions as hypothyroidism and dysmenorrhoea, and is, he thinks, effective if administered by the mouth.

It is not suggested that the ovarian pituitary endocrine mechanism is the sole factor in producing labour pains. No doubt the foetus itself acts as a direct stimulus, and without the foetus the intense muscular contractions would not occur, but it seems equally clear that the onset of labour cannot easily be accounted for without postulating some further exciting cause apart from the foetus and uterus.

Oestrogen, which I have examined from several sources, has not this action on the pituitary secretion. Oestrogen is especially effective in bringing on abortion in the early stages of labour, and Dr. Addison will explain what the effect of ovarian extract in the later stages of pregnancy may be.

In conclusion, no romance can be more remarkable than the fact that doctors, by using pituitary extract to stimulate the uterus in pregnancy, even to the exclusion of ergot, should have adopted the method which Nature has herself employed from times immemorial.

## DISCUSSION

Dr. KATHARINE A. COWARD (London) said that the standardization of ovarian extracts was based on their power to induce oestrus in ovariectomized animals but the dose of any extract required to produce this condition in a rat varied so much that a large number of animals had to be used for the assay. A "curve of response" had been drawn up on the results of subcutaneous injections of different doses of a particular sample of ovarian extract to ovariectomized rats. It took the form of a somewhat flat S shaped curve. It was significant that while some rats responded to a dose of 25 mg. of this extract some did not respond even to a dose of 175 mg. The doses of 25, 75, 125, 175 mg. respectively were given at fortnightly intervals then a dose of 10 mg. was given and the number of animals responding fell exactly on the curve which had been drawn through the first four points, which indicated that the extract had not deteriorated in value nor had the rats become less sensitive. Half the rats were then given another dose of 10 mg. subcutaneously, and half were given the same dose intraperitoneally. There was no significant difference between the results of the two methods of injection. Injecting the dose in three small parts at intervals of four hours did not make the response any better than injecting the whole dose at one time. The unit of oestrus was defined as that amount which would produce oestrus in 50 per cent of the animals tested, twenty animals being used for each test. When the response to a given dose had been found reference to the curve would give the dose required for a 50 per cent response and the assay of the material could be given as 1 unit per mg. or as x units per ccm. A salivary test was performed at the same time on 70 ovariectomized mice, using exactly the same doses of the extract as those employed in the rat experiment. It was surprising to find from the identity of the curves that the response in the mouse was equal to the mouse unit and was, therefore, quite independent of the weight of the two species or animal. In the rat experiment it was also noted that the response to a given dose bore no relation to the weight of the animal.

Dr. A. S. PARKES (London) discussed the interaction of the oestrus-producing stimulus with the corpus luteum and the function of the corpus luteum in maintaining pregnancy. There was much definite evidence that one function of the persistent corpus luteum was the inhibition of oestrus and ovulation during pregnancy and in the last few years it had been found possible to simulate this action by inhibiting oestrus and ovulation in the normal animal by the injection of extracts of corpus luteum. Since it was possible to override the oestrus-inhibiting power of the persistent corpus luteum by the injection of the oestrus-producing hormone the conception was suggested of an alternating dominance of oestrus producer and oestrus inhibitor, it being possible to override each in its normally dominant phase by the artificial augmentation of the other. As regards the function of the corpus luteum in maintaining pregnancy, many experiments on the elimination of the corpora lutea had shown that the corpora were necessary during at least the greater part of gestation. These experiments had, however, not been entirely conclusive. To eliminate the corpora lutea double ovariectomy or manipulation of the ovary during the operation had always been employed. The latter operation was of necessity attended by a considerable operation shock while the former abolished all ovarian activity. To overcome these difficulties the following technique had been devised. Young mice were sterilized unilaterally by x-rays and the animals which adult thus possessed one normal ovary containing both Graafian follicles and corpora lutea while the other ovary had neither but was expirable as already shown, of performing all ovarian endocrine functions except these associated with the corpora lutea. The animals were then allowed to become pregnant, and at various stages of pregnancy one or other ovary was removed. Animals in which the ovary removed was that containing the corpora lutea invariably aborted or reabsorbed the foetus, while those in which the sterile ovary was removed had in every instance an uninterrupted gestation. With any possible

operation shock thus controlled, these experiments had seemed to show definitely that in the mouse at any rate the presence of corpora lutea was essential for the normal progress of pregnancy. As regards the light thrown by these experiments on the mechanism of parturition it was very doubtful whether the normal atrophy of the corpus luteum towards the end of pregnancy could be compared with its experimental elimination earlier. There was much evidence which seemed to show that in ovarian pituitary parturition mechanism was set in motion by this normal atrophy of the corpus luteum, but in view of the relative insensitivity of the uterus to pituitary during early pregnancy, it was probable that the abortion which followed early removal of the corpora was not dependent upon such a mechanism.

Dr. W. R. ADAMS (Manchester) described the use of ovarian extract without the corpus luteum in the induction of labour and in dysmenorrhoea due to inadequate uterine contractions. In the first case five intramuscular injections each of 1 ccm. of ovarian extracts were given at three hourly intervals. If these failed the injections were repeated after an interval of twenty-four hours. The uterine contractions being kept under continual observation. In 50 cases so treated there were 4 failures. 31 patients were primiparae. The average duration of labour was first stage, twenty-three hours; second stage, two and a half hours; and third stage, fifteen minutes. All the children were born alive and well. The patient hardly felt the uterine contractions during the first stage—a point of considerable interest, and comparable with intestinal and rectal muscular contractions as well as with the freedom from pain during labour which occurred in some less civilized peoples. It appeared, therefore, that the ovary produced a hormone which acted specifically on the uterus, originating a bipolar action directly through the autonomic system.

Dr. W. F. T. HARTMAN (Edinburgh) said that it had been his practice for at least five years in cases where both ovaries had been removed either with or without the uterus, to give such patients a course of ovarian extract beginning on the fifth day following operation by giving 5 grains three times a day and continuing it for two months. For the next two months 5 grains were taken twice a day, and for the fifth and six months following operation 5 grains were given once a day—the idea being to minimize the menopausal symptoms by decreasing doses of ovarian extract. If the symptoms became more severe the dose was increased. Out of 31 patients so treated 24 took ovarian extract for one month or more, and there were 7 who did not. The latter including principally hysterectomy and salpingo-oophorectomy cases. The general health was improved in 19, 12 patients became content and of these 6 were cases of salpingo-oophorectomy and under 40 years of age. 9 had periods of depression. In 14 cases flushing were cured, in 7 slight, while three had practically no flushings at all. After a period of twelve months flushings were only present in 8, or these 6 were cases of salpingo-oophorectomy under the age of 40 in whom the uterus had been left. This result compared very favourably with the patients who had not taken ovarian extract for in 6 of the 7 who had not received it flushings were still present at the end of twelve months. Headaches occurred in 8 while nervous symptoms were manifested in 5. Flushings were very much improved by the treatment. The ovarian extract seemed to have helped the patients with regard to adipose headaches and nervous symptoms but not so all in regard to flushings. Dr. Hartman thought that when both ovaries had to be removed then the uterus should be taken out also especially in cases of chronic or purulent salpingitis. The ovarian extract had been administered orally and Dr. Hartman concluded that it was given hypodermically once or twice a week following operation the results would be even better.

Dr. W. KENNEDY (Edinburgh) believed that the disappointing nature of ovarian medication was due to the very diverse and sometimes unscientific methods adopted. The

species and oestrous period of the animal from which the gland was derived, the methods of extraction and of exhibition, and the diseases for which the substances had been used were all of prime importance. Dr J C Hirst had shown that the intravenous administration of corpus luteum in the pernicious vomiting of pregnancy was effective. The speaker had also found that the corpus luteum would inhibit ovulation, and indeed in continued dosage would produce extreme degeneration of the follicular apparatus. The evidence was not plentiful, but it was very probable that there was a direct relationship between ovarian function and the blood sugar level. The speaker was surprised that Miss Coward had found mouse and rat units identical in oestrum standardization, as this was contrary to the usual finding. Further, it was undoubted that the luteal cells arose from the theca interna in some animals, the membrana granulosa in others, and possibly from both in some others. It was, therefore, necessary to specify the species in any assertion as to the endocrine function of these cells.

Dr DAVID CAMPBELL (Glasgow) raised the question whether the injection of ovarian extract into animals had any inhibiting effect on the activity of insulin. With Dr Scott he was investigating this point, and up to that time then results were as follows: (1) Subcutaneous injection of oestrum or the lipo-soluble ovarian hormone and of watery extracts of the ovary had no effect on the blood sugar of a normal animal. (2) Subcutaneous injection of oestrum twenty-four hours before, and again simultaneously with, insulin injection had no inhibiting effect on the action of insulin when compared with control experiments. (3) Subcutaneous injection of watery extracts of ovary given at the same time as insulin had no inhibiting effect on the action of insulin when compared with control experiments. Dr Dixon, however, in his experiments, had used the intravenous route, and had showed that the apparent effect on the pituitary gland was transitory, lasting only ten to twelve minutes. Dr Campbell had tried to determine whether the intravenous injection of watery extracts would have any effect on the blood sugar of an animal in the state of insulin hypoglycaemia. These experiments had not progressed very far, but up to the present there was no evidence to suggest that it did inhibit insulin activity; occasionally the reverse effect had been observed. It might be that they had used extracts of ovaries taken at a time when there was no hormone present, and it was necessary to investigate this point further before they could say definitely that ovarian extracts had no inhibiting effect on insulin activity through the medium of the pituitary gland.

Professor C W GREENE (United States of America) called attention to work by Professor Edgwin Allen of the University of Missouri, who was a pioneer in the discovery and scientific testing of oestrum. Professor Allen had recently been testing the reactions of ovariectomized monkeys. His publications on this new work had not yet crossed the Atlantic. Allen first established the sexual cycle of individual monkeys and then removed the ovaries. Follicular extracts were then given in repeated doses. The animals reacted with all the phenomena of the normal oestrus—reddening and swelling of the skin of the vulva, reddening of the ischia and adjacent skin, and growth of the mammary glands. The uterine-vaginal growth changes occurred as in the normal, and menstrual bleeding actually occurred in these test monkeys.

Dr DIXON, in reply, briefly referred to the work of Dr Addis, and had stress on the fact that the action of pituitary extract was essentially to render the uterus sensitive to any form of stimulus. Dr Addis and he were in entire agreement regarding facts, but Dr Addis thought that the ovary acted directly. All previous investigators were agreed that it exerted no such action. In reply to Dr Campbell he referred to a paper written by Dr Waddell and himself and published in the *BRITISH MEDICAL JOURNAL*, showing that insulin also excited the pituitary gland to secrete as it did other endocrine glands. He referred

finally to the primary work of Allen and Davis and explained to Professor Greene that it the names of the two investigators had not been mentioned in the discussion, it was not that their pioneer efforts had not been appreciated, but rather because their conclusions were generally known and accepted.

## THE CLINICAL FEATURES OF ECTOPIC PREGNANCY

BY

DANIEL DOUGAL, V.C., M.D. MANCHESTER,  
Professor of Obstetrics and Gynaecology, University of Manchester  
Honorary Assistant Gynaecological Surgeon,  
Manchester Royal Infirmary, Honorary Surgeon,  
St Mary's Hospitals, Manchester

THERE is an extensive and very complete literature on the subject of ectopic pregnancy, and I cannot hope to add anything new to what has already been written. In the early part of this year, however, I reviewed a hundred cases operated upon by myself, and it may be of interest to refer to some of the main clinical features in the light of the results obtained from analysis of that series.

Pregnancy in one of the Fallopian tube is by far the most common variety, and is all my cases come under that heading I propose to leave out of account the other and rarer forms. I will also say very little about the pathological anatomy of ectopic pregnancy, except to mention the frequency of the various terminations found at the time of operation in my own cases.

Tubal abortion occurred in 52 per cent, tubal rupture in 37 per cent, and the tubes were unruptured and unaborting in 12 per cent. A tubal mole was present in nearly 80 per cent of the cases.

### ETIOLOGY

Most authorities agree that the chief predisposing cause of ectopic pregnancy is a preceding pelvic infection which so damages the Fallopian tubes as to obstruct or delay the passage of the fertilized ovum to the uterine cavity. The results of pelvic infection may be visible to the naked eye at the time of operation in the form of adhesions, especially about the non-gravid tube, and the frequency of this factor can therefore be determined with some accuracy. It has to be remembered, however, that gonococcal infection may be limited in its results to the tubal mucosa, and be incapable of demonstration except by careful histological examination.

In my own series old-standing adhesions about the non-gravid tube were observed in 50 per cent of the cases, but as this leaves out of account those in which the gravid tube only was affected or the mucous membrane alone damaged, it will be realized that the percentage is probably much higher.

Gonorrhoea and puerperal septic infections are undoubtedly mainly responsible for the pelvic inflammatory lesions, but appendicitis and abdominal tuberculosis are also important. There were four patients who had had previous operations for appendicitis, and in the course of my own operations I found the appendix adherent in twelve cases, in ten of which it was found necessary to remove it. The appendix was not always examined, however, so the incidence of this source of infection is probably greater than I have indicated. In this connexion it is interesting to note that tubal pregnancy is somewhat more common on the right side—59 per cent as against 41 per cent in my own series.

Developmental abnormalities such as tubal diverticula and distortion of the tubes by tumours, also play a part, though I think it must be a very subsidiary one. I found only one example of developmental abnormality, a double uterus, and the malformation was probably in no way responsible for the ectopic pregnancy. I believe that tumours were observed in two cases (about 2 per cent), but in both instances the tumours were small and situated near the uterine cornua.

There are certain other factors which have been suggested

the question of etiology. Age in itself is of little importance: the youngest patient was 21 years of age, the most elderly 43 years, and the majority were between the ages of 20 and 35 years. In 40 per cent the condition occurred during the first five years of married life and 35 per cent during the second five years. In about 10 per cent the patient had been married one year or less (the shortest period was seven weeks) and in every one of these the ectopic was the first pregnancy. Evidence of previous pelvic infection was present in only one case, so there must obviously be some other cause to seek in the case of recently married and apparently healthy young women who start their child bearing career with an extruterine pregnancy.

Nearly one-third of the cases had never had a previous uterine pregnancy, of these 2 were single, 8 had been married one year or less (shortest period seven weeks), 5 one to two years, 5 two to three years, 3 four to five years, and 9 more than five years (longest period ten years).

The proportion of uterine abortions to full term pregnancies was not abnormally large, but it was noticed that the last pregnancy terminated in abortion in 20 per cent of the cases, and in 10 per cent this abortion was the only previous pregnancy.

The interval between the last uterine pregnancy and the operation for ectopic gestation exceeded three years in 55 per cent and five years in 31 per cent of cases, this lends some support to the view frequently put forward that ectopic pregnancy commonly follows a period of sterility. The shortest interval in the series was seven months but I know of one case operated upon by a colleague within four months of a full term labour.

#### DIAGNOSIS

The diagnosis of ectopic pregnancy is based upon a symptom-complex which includes one or more of the three cardinal symptoms—amenorrhoea, irregular uterine haemorrhage and abdominal pain. Pain on defaecation is also important but is not encountered with the same frequency.

John Morley has pointed out that shoulder tip pain is not infrequently met with in the graver forms of tubal rupture where the peritoneal cavity is suddenly flooded with blood. In the general run of cases dealt with by the gynaecologist this symptom will not be met with very often but in those very acute cases often diagnosed merely as acute abdomens and sent into a general hospital it will no doubt be found much more frequently.

Amenorrhoea I found present in 72 per cent of my cases. I include of course those cases where the patient merely goes a few days or perhaps a week or two over her period and then commences with uterine haemorrhage. The latter constitute the vast majority in any series as it is unusual to find a longer period of amenorrhoea than two months. Amongst my own cases there were only two in which the foetus was of more than two months development.

Abdominal pain is practically always present as I found it in 97 per cent of cases. It varies in character and degree according to the lesion, but it is generally sufficiently prominent to indicate to the patient that something is wrong. The colicky pain associated with a pregnancy still in the tube or in process of abortion is almost invariably situated on the same side as the gestation although I have seen the contrary stated. The acute lancinating pain met with in cases of diffuse intraperitoneal haemorrhage is definite striking and requires no further elaboration. There is also a more diffuse pain associated with gradual leakage of blood or repeated small haemorrhages into the abdomen and the formation of protective adhesions.

Irregular uterine haemorrhage was found in 82 per cent. The blood was almost invariably moderate in amount and dark in colour with an appearance which has been likened to prune juice or black-current jam. Very occasionally the blood was brighter in colour and more profuse and in these I think that the uterine decidua was actually in process of separation.

The old explanation that the uterine haemorrhage is the result of decidual separation or a dislodgement is obviously

not complete since it is well known that it may persist after the decidua has been completely expelled and even after the uterine cavity has been curetted. On the other hand the haemorrhage ceases almost immediately when the gravid tube has been removed, the only exceptions being those cases where the decidua is incompletely separated and is still in the uterus at the time of operation. Simpson believes that the haemorrhage is due to subinvolution the process of involution being delayed by an incomplete termination of the tubal pregnancy. In other words, some of the chorionic villi are still alive in the tube and are able to exert their stimulus upon the uterus.

The importance of the three main symptoms depends upon their presence in combination and not individually, and an examination of the histories of my own cases shows to what extent they can be depended upon in this respect. Amenorrhoea, uterine haemorrhage and abdominal pain were present in 64 per cent. Bleeding and abdominal pain occurred in 24 per cent. Amenorrhoea and abdominal pain were found in 4 per cent, amenorrhoea and bleeding in 3 per cent, and abdominal pain only in 3 per cent. From these figures it would appear that all three cardinal symptoms may be expected in six out of every ten cases and when characteristically present a correct diagnosis of ectopic pregnancy should be made without difficulty. The order of their occurrence was usually found to be amenorrhoea, abdominal pain and then uterine haemorrhage.

The complete clinical picture varies according to the lesion present and it is convenient to divide the cases into the following three groups or clinical types.

1 Cases in which the ovum remains in the tube and there has been little or no haemorrhage into the abdomen. There were 14 of my cases in this group, or 13 per cent.

2 Cases in which rupture or abortion has occurred with diffuse intraperitoneal haemorrhage—29 cases or 27.6 per cent.

3 Cases in which rupture or abortion has taken place with gradual or repeated haemorrhage into the abdomen—62 cases, or 60 per cent.

In Group 1 are included those cases in which the pregnancy is intact and also those in which a blood mole has formed. In the latter a definite group of symptoms and physical signs can usually be obtained but in the former it is doubtful if a definite diagnosis will be possible.

The patient complains of colicky pain in one or other iliac fossa and frequently of irregular uterine haemorrhage dark in colour and moderate in amount. The bleeding can in no sense be described as a flooding. She will generally have gone a week or so over her period and other signs and symptoms suggestive of early pregnancy may be present. She is not acutely ill, but may look quite definitely out of sorts.

Abdominal examination will yield little information except perhaps some tenderness on pressure over one iliac fossa. On vaginal examination the uterus may feel somewhat enlarged and it will usually be possible to make out through one or other lateral fornix a tender elastic sausage-shaped swelling. In many cases, however, the physical signs will be inconclusive and in these the advisability of careful examination under anaesthesia should be seriously considered.

In the differential diagnosis appendicitis, threatened uterine abort or inflammatory tubal swellings and small ovarian or broad ligament cysts possibly associated with a uterine pregnancy will present the greatest difficulties.

When the gestation is in the right tube the condition is apt to be mistaken for appendicitis, the patient being sent into the surgical wards of a general hospital. Appendicitis, however, presents a very definite symptom sequence—namely pain usually epigastric or umbilical nausea or vomiting local iliac tenderness fever and leucocytosis—and this will not be observed in cases of ectopic gestation. Nor will there be found in appendicitis a combination of any symptom or signs suggesting a pelvic origin—for example amenorrhoea, uterine haemorrhage and tender extracervical swelling.

threatened uterine abortion should present little difficulty. There will be definite enlargement of the uterus, with, perhaps, some dilatation of the cervix, pain, if present, will be in the back or hypogastrium, the bleeding will be more profuse, bright in colour, and possibly associated with the passage of some clots, and there will be no extrauterine swellings to be palpated.

Inflammatory tubal swellings, when mistaken for ectopic pregnancies belonging to this group, will generally be of the subacute or chronic variety, and will often be bilateral. There will usually be a longer history, vaginal discharge will have been complained of, amenorrhoea will be absent, and menstruation, if affected at all, will usually be too frequent and the loss excessive.

Where a small ovarian or broad ligament cyst is associated with an early pregnancy the diagnosis is apt to be more difficult, but here again the character of the haemorrhage, if present, will afford a clue. If no haemorrhage be present the uterus will be found definitely enlarged and soft, and the extrauterine swelling not usually tender. The swelling will also have thinner walls, and feel more cystic than a gravid tube, points easily made out and of great value in clearing up the diagnosis.

In Group 2 there are also two varieties. In one the haemorrhage is sufficient to prostrate the patient, who either dies or is operated upon immediately. In the other she reacts, and if not operated upon during the acute attack manages to weather the storm, and when dealt with surgically at a later period will present the characteristics of a case belonging to Group 3. To these Schumann has applied the terms asthenic and sthenic respectively.

In the asthenic variety the patient is suddenly seized with an agonizing and lincinating pain in the lower abdomen, accompanied by extreme nausea and vomiting, syncope, collapse, and shock rapidly follow. The pulse becomes thin and rapid, the temperature is subnormal, the features are pallid, the skin is cold, clammy, and blinched, the respirations become shallow and rapid with frequent sighing, the pupils are contracted, and the expression is anxious. There is intense restlessness and thirst. On examination the abdomen is found somewhat distended and resistant to pressure, and it may be possible to demonstrate the presence of free fluid. Tenderness and rigidity will be noted in some cases, but not in all, depending, no doubt, on the time which has elapsed since the actual rupture or abortion took place. On vaginal examination it will usually be possible to detect a fullness in the posterior fornix, or even a doughy feeling if clots be present. The affected tube may or may not be palpated. The sudden onset of symptoms and the general appearance of the patient will frequently be the chief points on which a diagnosis is made, but they are sufficiently characteristic to warrant this in nearly every case.

In the sthenic type the onset is very much the same, but the patient rallies in a short time and the pain becomes less acute. The temperature rises to  $101^{\circ}$  or higher, and the pulse remains full and strong and is not unduly rapid. The expression is anxious, the skin is not usually pallid, and the mucous membranes are not blanched. The abdomen is distended, and extremely tender to pressure. Rectus rigidity is the rule, and is usually more intense on the affected side. Shoulder-tip pain may sometimes be elicited. There is tenderness on vaginal examination and a sensation of fullness or a doughy feeling through the posterior fornix is before.

The descriptions I have given of the two types of cases are taken largely from Schumann's excellent monograph on extrauterine pregnancy, and agree with my own observations in cases belonging to this group. In the differential diagnosis various acute abdominal conditions, such as perforation of the stomach, gall bladder, or appendix, have to be excluded, but the history of the case, the sudden onset, and the persistence of extreme pallor and subnormal temperature without rigidity of the abdominal wall, in a patient previously well except for some menstrual irregularity, seldom or never leave room for doubt. (Zachary Cope.)

The sthenic type of case may be mistaken for an acute salpingitis and treated expectantly for a time. Amenorrhoea followed by bleeding is occasionally found in these

cases, so a correct diagnosis will have to be based on the short and characteristic ectopic history and the presence or otherwise of a purulent vaginal discharge or other symptoms pointing to a recent pelvic infection.

Group 3 will always comprise the majority of cases in any series, and the clinical picture will vary from that of an acute and dangerous illness to what may fairly be described as a chronic disability. The most serious cases will include those from Group 2 already referred to, and also a certain number (ten in my series) in which the amount of encysted blood is sufficiently large to form a definite tumour capable of displacing neighbouring structures and possibly reaching above the pelvic brim.

The patient complains of abdominal pain of moderate severity and usually situated in one or other iliac fossa, though later it may be diffused over the lower abdomen. There will nearly always be irregular uterine haemorrhage of the characteristic ectopic type. Careful investigation of the history will usually discover a short period of amenorrhoea followed by uterine bleeding of varying duration. A severe attack of pain followed by collapse may have occurred, or there may have been several less severe attacks accompanied by momentary faintness.

Pain on defecation is commonly met with, and sometimes dyspnoea. If the amount of blood in the pelvis be large there may be constipation amounting to obstruction, or painful or frequent micturition, or even retention of urine. The patient looks ill, though usually not acutely so, and there is generally some degree of anaemia. The temperature is slightly higher than normal, and may occasionally be over  $100^{\circ}$ . The abdomen is tender on pressure, especially over the affected side, but there is no rigidity. There may be a sensation of resistance over the pelvic brim or a definite tumour may be palpated. In the latter case the percussion note is partly dull and partly tympanic, the mass consists of both blood clot and adherent intestine.

Vaginal examination will reveal a tender mass in one or other lateral fornix, and if the blood in the pouch of Douglas be clotted a tumour will be felt through the posterior fornix also. When a large haematocoele is present the uterus will usually be displaced forwards and upwards, but if there has been bleeding into the broad ligament with the formation of a haematoma, the uterus will be pushed over to the opposite side.

Cases belonging to this group have to be distinguished from pelvic appendicitis, pyosalpinx, and retention of the gravid uterus. Pelvic appendicitis is particularly difficult to exclude, as it may give rise to nearly all the signs and symptoms of a small pelvic haematocoele. Hypogastric pain, vomiting, local tenderness, slight fever, and tenderness on rectal and vaginal examination are frequently present in both conditions, and in neither case will one expect abdominal wall rigidity. (Zachary Cope.)

In ectopic pregnancy, however, there is nearly always some amenorrhoea or menstrual irregularity, characteristic uterine haemorrhage, the appearance of anaemia, and the initial attack of pain and faintness suggestive of intraperitoneal haemorrhage. In pyosalpinx the characteristic ectopic history will be absent, there will be a longer history of ill health, and some evidence of previous pelvic inflammation. There may be some menstrual irregularity, but rarely amenorrhoea. On vaginal examination the doughy mass in the posterior fornix will be absent.

A retroverted gravid uterus should present no difficulty in diagnosis unless the tubal pregnancy has gone on to the third or fourth month. There will be a history of three third or four months' amenorrhoea, with the characteristic appearance of bladder symptoms during the fourth month, and the other signs and symptoms of uterine pregnancy will be well marked. If a catheter be passed and the bladder emptied, the absence of the uterine fundus from its proper position will be noted.

#### TREATMENT

The treatment of ectopic pregnancy is surgical, and in my opinion the sooner operation is performed the better for the patient. Expectant treatment is dangerous, as it is impossible to forecast when another and possibly fatal haemorrhage may occur. In a few of my series of cases, where shock is profound and the patient practically

patients it may be advisable to improve the general condition before submitting her to the additional strain of a lipostomy, but if this line of treatment is to be followed the patient must be in hospital or nursing home, and under constant observation as she may have to be taken to the operating theatre immediately should there be any indication of further haemorrhage.

The particular operation performed will depend on the type of case and the condition of the patient. In serious cases nothing more should be done than is actually required to save the patient's life, and this generally means excision of the affected tube with or without the corresponding ovary. No time need be lost in attempting to clear the peritoneal cavity of all blood clot. When the case is subacute and the pelvic organs are disorganized or the seat of an old infective lesion it is quite justifiable to remove both appendages or even the uterus.

Some advocates of conservative surgery have urged that the gravid tube should be saved whenever possible, but this view has not received general support. The danger of another pregnancy occurring in the same tube is probably not a remote one so most operators prefer to err on the safe side and remove it. A second ectopic gestation not uncommonly occurs in the remaining tube and there are those who would guard against this accident by always removing both tubes when operating for tubal pregnancy. This is going too far in the other direction since many of the patients have normal pregnancies subsequently if the non-gravid tube be left intact.

The operations are carried out abdominally, the only exceptions being those rare cases in which a pelvic haematocoele has become infected. In such an event the correct line of treatment is to open the posterior fornix and evacuate the infected clot. One of my own patients in whom this operation was performed subsequently became pregnant and was delivered of a healthy child.

The operations performed in my series of cases were as follows:

Unilateral salpingectomy	10 cases
Unilateral salpingo-oophorectomy	55
Double salpingo-oophorectomy	8
Subtotal hysterectomy with removal of both appendages	30
Posterior colpotomy (for infected haematocoele)	2

#### RESULTS

The prognosis in cases submitted to operation is good, and the earlier operation is performed the better the results. I know of no disease or parallel severity where the response to prompt surgical treatment is so rapid or so satisfactory. There are no doubt many patients who die before surgical treatment is available but the number of these cases will become smaller as the symptoms and signs antecedent to rupture become more generally recognized. There were no deaths in my series and this I must attribute to good fortune though it bears out what I have said about the remarkable powers of recovery which these patients display after operation.

In conclusion I will add a few words about the question of subsequent pregnancies.

Excluding those operated upon less than six months before the date of my investigation there were 53 cases where subsequent pregnancy was possible. 14 could not be traced, which reduces the number to 39. Of these 46 per cent had a subsequent uterine pregnancy and 13 per cent a second ectopic pregnancy. In 41 per cent there was no further pregnancy.

The figures show that the prognosis as regards subsequent pregnancies is fairly good but that there is a very definite risk of the patient getting a second ectopic pregnancy. As a matter of fact 7 of the 100 patients in my series had two ectopic gestations and in 5 of them I performed both operations myself. In these 5 cases the non-gravid tube was apparently healthy at the time of the first operation.

#### DISCUSSION

Miss MABEL I. RIMMAY (Plymouth) related her experience of a case of undoubtedly ectopic pregnancy for which no operation was performed. At the necropsy fifteen years later there was no sign of pelvic disease.

Dr JOHN MURRAY (Liverpool) questioned the high incidence of tubal rupture in Dr Douglas's series. In his own series of 110 cases he had only found 7 cases of undoubtedly pathological rupture of the tube. He agreed that the great majority of cases were associated with pelvic disease in one form or another but in quite a number of cases trouble could be traced to the appendix, hence on every occasion when operating for this condition he removed the appendix when reasonably accessible.

Dr BRIAN L. SOMMONS (Dublin) referred to the biochemical tests which had been introduced to aid in the differential diagnosis. Cases of ectopic pregnancy had very frequently to be judged by their general appearance only. In undoubted cases of tubal rupture he was strongly against moving the patient, preferring to operate, if need be, on a cottage table.

Dr FRANKLIN MURRAY (Newcastle) said that in many cases all the signs were referred to the upper abdomen, so that a diagnosis of ruptured ulcer or biliary trouble might be made. In the early acute stages no blood could be detected in Douglas's pouch by vaginal examination alone, but only by combined rectal and vaginal examination. He thought that many patients were operated upon too late, a wonderful improvement often resulted if a short period was given to allow recovery from the shock or being moved.

Mr GORDON (Edinburgh) said that there was one type of case which was apt to be overlooked—namely rupture into the broad ligament. He had seen this several times and it was frequently mistaken for the retroflected gravid uterus since the symptoms might be the same. He emphasized the need for the very greatest care in examining a case of suspected ectopic pregnancy, rough handling might produce disastrous consequences.

Professor R. J. JOHNSTONE (Belfast) laid stress on the extreme tenderness felt on examination in the posterior fornix, and regarded this as a valuable aid in diagnosis.

Dr HAIG LERGTON (Edinburgh) commented on the importance of obtaining an early diagnosis. In his experience the mistake was not infrequently made of diagnosing these cases as ordinary abortions.

Dr DOUGLAS, in reply, said that he might have overestimated the number of tubal ruptures but he did not think he had. He had had no experience with biochemical tests in distinguishing these cases from those of pelvic infection. He had seen a number of cases where pain had been referred to the upper abdomen. He agreed as to the dangers of rough examination.

### COMPOUND COMMINUTED FRACTURE OF TIBIA AND FIBULA INVOLVING THE ANKLE—JOINT TREATED BY THE "BIPP METHOD"

A CASE REPORTED BY MONICA BELL, M.B. B.S. DUBLIN, HUNSMATCH-ON-TYNE

With Remarks by

RUTHERFORD MORISON, F.R.C.S.,

EXCERPTUS PROFESSOR OF SURGERY, DURHAM UNIVERSITY SCHOOL OF MEDICINE, NEWCASTLE-ON-TYNE

A GROOM, aged 30, was admitted to Hexham War Memorial Hospital on June 24th, 1927. Three hours before while cycling on the road, he was crushed against a wall by a motor car, and the near wheel of the car went over his right leg. He could see that his right foot was wired completely round and that the bones of the leg were sticking out through his torn clothing, and that there was a large wound. He took hold of his foot by the heel and toes and replaced the bones as well as he could.

CLINICAL NOTE BY DR. MONICA BELL

Condition on Admission

He was a thin middle-aged man and was suffering from severe shock. After a raw examination he was taken to the operating theatre and treated with open tibia by Dr. H. L. J., and operated upon by Dr. F. L. J.

## GAS IN THE PERITONEAL CAVITY

[THE BRITISH  
MEDICAL JOURNAL]

Two large wounds smeared with dirt and motor oil were seen on the inner and outer sides of the lower end of the leg and ankle joint. After enlarging these wounds several fragments of the tibia lying completely detached, were removed and a considerable tag of soiled, hopelessly lacerated muscle, hanging out of the inner wound was excised. The upper cartilaginous surface of the astragalus was visible through the widely opened ankle joint. A few small bleeding vessels were ligatured the wounds, treated by the hipp method, were sutured by silkworm gut sutures and the leg was fixed between two lateral Gooch splints extending from the tubercle of the tibia above to the sole of the foot below.

## After Progress

The symptoms of shock soon disappeared after he was put to bed and his leg felt comfortably free from pain. After the second night pulse and temperature remained normal. After the no discharge appeared through the dressings and they were left unchanged for ten days. Then the wounds were found to be healed except where a small tag of muscle had been left projecting from the inner wound, uncovered by skin. The sutures were all removed. The small granulating wound over exposed muscle dried up without showing any sign of infection and the scrub separated in three weeks. From this time his recovery was uninterrupted.

## REMARKS BY PROFESSOR RUTHERFORD MORISON

I saw this patient at the request of Dr. Monica Bell, to whom I am indebted for notes of the case, three months after the accident described. She wished to be advised when it would be safe to allow her patient to begin to walk. He had been getting about on crutches and undergoing massage treatment. There was still some swelling of his ankle, but the fracture result was excellent and the movements of the ankle-joint were limited to about half of the normal, but were steadily improving. He is now doing his work with the help of a crutch, to be used for about three months.

During the war I proved that with the aid of suitable antiseptics infected wounds could be safely closed, and that it was possible to obtain "healing by first intention" in many of them. This was to me a new and surprising discovery, as it was to many of the visitors who came to see our work in the Northumberland War Hospital. It also confirms my belief that the greatest advance in surgery depends upon the discovery of new and more efficient germicides, just as the treatment of syphilis did. The general practitioner is in danger of losing acquaintance with Lister's principles of wound treatment and their application by the use of antiseptics, because aseptic methods are now used to the exclusion of everything else in all hospitals. With a trained staff and fully equipped service such ideal aims are justified by results, but they never will be in ordinary everyday surgical work, and patients have to pay the penalty for lack of this knowledge of the use of antiseptics.

The *Hipp Method of Treatment of War Wounds*, published by the Oxford Press (price 2s. 6d.), describes fully our practice. Numerous papers from others, as well as by myself have described the remarkable results achieved, of which the case recorded is a good example. The only explanation I can offer is to why this method has not been adopted universally is that cases of poisoning, occasionally fatal have followed it. From the first I pointed out the risk of poisoning by absorption of the measurements and a few of our early cases developed these symptoms of which I fully described. Or my later colleagues we had learned a better technique, none were all but in exceptional cases showed the blue line characteristic of bismuth absorption. Or the hundreds of cases treated in the Northumberland War Hospital by my colleagues and myself none died of hipp poisoning. The only critic in possible is that our directions had not been followed with the necessary care in fatal cases. Few alterations have been made in our method, and the latest directions are:

1. Under an aethetic usually open ether, cover the wound with gauze wing out of 1 in 20 carbolic acid, and thoroughly clean the skin and the surrounding area with

the same lotion. (Preliminary washing, by cleansing, swelling of the epidermic cells, prevents penetration of the carbolic solution, and so does harm.) Drape the surrounding area with towels wing out of 1 in 20 carbolic acid, and with gloves and instruments in the same.

2. Open the wound freely, and if possible sufficiently to permit of inspection of its cavity. A guide—finger is the best if the size of the opening permits of it, and, if not, a thick probe—should be introduced to the bottom of the wound, and held there until fully exposed. In doing this special regard must be paid to nerve trunks and muscular branches of nerves, since the division of blood vessels, excepting the ligament, and of muscles themselves does little harm as compared with that of the disability following nerve damage. Cleanse the cavity with dry sterile gauze mops, Volkmann's spoon, etc., and remove all dead tissue.

3. Mop the surrounding skin and the wound cavity with methylated spirit, and dry it.  
4. Fill up the wound with hipp, and rub it well in with dry gauze (clean hands and rubber gloves, of course, understood). Then remove all excess, leaving only a thin smear covering over the wounded surface. (In bone fractures) Dress the wound with a tip of gauze wing, bone acid powder, and cover all with an absorbent pad. This dressing requires no change for days or weeks if the patient is free from pain or constitutional disturbance. If bloody discharge comes through, the stained pad may be soaked in spirit, and a gauze dressing wing out of the same applied as a further covering, or re-dressing is very easily done. After removal of the old dressing, the wound is covered with a dossil of wool soaked in spirit, and my dressing is wiped off the surrounding skin till it is clean. A dressing like the first is then applied when necessary. Hipp should never be used as a "slive." Rubbed on cracks, squeezed into sinuses, spread over septic ulcers, it may cause a severe septic "flu up"—a dangerous and disconcerting result of treatment.

## GAS IN THE PERITONEAL CAVITY

BY  
W. MCADAM FORTIS, M.S., F.R.C.S.,  
SURGEON TO ST. BARTHOLOMEW'S HOSPITAL.

The peritoneal cavity in the male is a closed sac. Into this cavity there is secreted or excreted normally a small quantity of serous fluid which serves mainly as a lubricant. Gas in the space is an alien. The peritoneal cavity in the female is not closed to the atmosphere for an canal theoretically pass through the vulval outlet into the vaginal passage, up through the cervical canal, the cavity of the body of the uterus, along a Fallopian tube, and so it is fibrillated end into the cavity of the peritoneum. That it may actually do so may be surmised by the fact that an ill enter, by suction, the vaginal space when the female is in the genu-pectoral position and the labia are parted. Further "inspiration" may carry it to the level of the rest of the female genital tract, and a chthonic peritoneal cavity. If it does it will act as a toxic substance, and may even cause some collapse by its sucking action. It is possibly the reason why some patients felt abdominal or the uterus is perforated by a sharp instrument. To put it briefly the tract along which spermatozoa travel is also open to liquid and gas.

## Gastric Gas in the Peritoneal Cavity

Gastric gas is the type of gas which is secreted by the wall of the peritoneal cavity. Perforation of the wall, or the wall of the duodenum by the contents of the stomach, is the usual cause of its entry into the peritoneum. As the nature of the gas is not known by analysis, the patient is not told what it is, and hold the abdominal muscle tight. It is

pus between the liver and the diaphragm so that the normal area of liver dullness may be diminished or even lost. It is, however, unjustifiable to wait for this sign before undertaking laparotomy in perforation.

### Intestinal Gas in the Peritoneal Cavity

It is not so common for gas from the intestines to pass into the peritoneal cavity. Occasionally in ulcer usually a typhoid one perforates the ileum near the caecum and again intense agony follows. But little gas escapes and a recurrent appendix perforates probably owing to the fact that the inflammation has blocked the connection with the caecal cavity. Here the very irritating fluid contents of the appendicular cavity produce the pain. Perforation of the colon by carcinoma or of the rectum in a blow septic and irritating gas to pass into the peritoneal cavity.

The question whether intestinal gas can pass through the unperforated and non-inflamed wall of the small or large intestine is one of great interest. Intense distension of the large intestine may occur usually in some form of very chronic intestinal obstruction and the wall of the bowel becomes so thin that it would seem as if it must give way and yet it very rarely does so. In the extreme cases gas by a fine trocar and cannula and in some cases with temporary success. When this has been done by a deliberate puncture through the abdominal wall and into the intestine the door would appear to be opened for intestinal gas to pass out. Possibly in such cases the intestinal gas is not very septic and but little of it reaches the actual peritoneal cavity—no passing out through the cannula.

Cases have been recorded in which gas has passed from the unbroken wall of the intestine into the general peritoneal cavity. The exact manner in which this occurred it is difficult to say. The gas itself appears in the circumstances to be aseptic and therefore innocuous. The following is a deeply interesting case of this nature.

A lady now aged 61 had the following history. In 1911 from the first she had pain at the menstrual periods. At the age of 21 she had a carriage accident. At 25 she was said to have a tumour in the abdomen (intestinal distension). She saw a physician in Harley Street who advised her not to have any operation but further advised her not to walk. But she did continue to walk and did not appear to be the worse for it. It is possible that the exercise helped to expel flatulence. From 20 years of age the abdomen had gradually become more distended and at times remarkably so. While there was no pain it was never really severe up to 44 years and vomiting only occurred now and again. About the age of 45 she began to have attacks of great distension with acute pain. She became utterly unnerved thereby and at times had neurotic paralysis of limbs.

### First Operation—Laparotomy

In June 1913 the abdomen was explored by a very competent provincial surgeon who found much distension of the large intestine but nothing radical was done. For a while she was distinctly better and distension being less but a year later she was as bad as ever. Examination by x-rays at this juncture merely revealed great colon stasis and left her with a troublesome burr. It was then (in 1916) that I saw her for the first time.

### First Ileosigmoidotomy

On June 7th of that year I explored the abdomen and determined to try the effect of a large ileosigmoidotomy. The result of this was perfect for three years as distension and pain vanished. Then gradually all her old symptoms reappeared.

### Second Ileosigmoidotomy

In October 1920 I saw her again. From examination I came to the conclusion that the ileo-colic anastomosis was faulty in its functioning. She would not hear of another x-ray examination so confirmation by a barium enema was faulty. As the previous operative measures had relieved her so greatly I was very desirous I should attempt one thing further and that by invagination of bowel wall the anastomosis itself admit the tips of the fingers easily. There was how ever considerable distension of small intestine and of large intestine proximal to the junction between them. After consultation I decided to make another ileosigmoidotomy close to the previous one in the hope that a very free intercommunication would relieve symptoms once more, and perhaps permanently.

Again she was pleased with the immediate result and left London rejoicing. But on April 20th 1924 three and a half years after the second anastomosis I received a letter from Dr F. M. Knott of Sutton Coldfield to say he had been called in to see her and she was distressed in pain and vomited occasionally. Feeling that further operation was not called I advised temporarily with enemas, pituitrin etc., and this treatment certainly gave some relief.

### Third Laparotomy—Large Catheter Tied In

She continued with bouts of distension and pain until the beginning of 1927 when her distress became very great chiefly because the pressure upon the diaphragm caused respiratory and cardiac embarrassment. I was asked by Dr W. Leslie of Penzance to go down to see her prepared to operate. Accordingly on February 26th I reopened the abdomen. There was no free gas in the peritoneal cavity but the small and large intestines were greatly distended leaving as it ready to burst. In order to make quite sure that one or other of the anastomoses was working I deliberately incised the sigmoid opposite the second junction. This caused a considerable quantity of odourless gas to escape from the lumen of the bowel. The stoma was perit. I then decided to pass a No. 12 oesophageal catheter (stomach tube) through the anus up the rectum into the colon and through the anastomosis. Considerable difficulty was experienced in manoeuvring the tube through the upper part of the rectum there being apparently at this spot a definite narrowing of the lumen. Eventually the catheter was manipulated to the whole distance and eventually it should not slip out it was tethered by a silk worm gut suture to the side of the anus. The incisions in the colon and in the abdominal wall were closed. The wound healed well. Dr Leslie reported that for four days whilst the tube was in it the distension remained in abeyance and the patient was much more comfortable. At my suggestion he removed the tube at the end of this time but she immediately began to distend once more and experienced considerable pain. In spite of enemata, pituitrin and strychnine only partial relief could be obtained. The reintroduction of the tube again brought about a reduction of the distension.

### Fourth Laparotomy—Gas in Peritoneal Cavity

On March 24th she passed a tubular cast or intestinal mucous membrane by the rectum after having had several loose motions but distension recurred and on March 25th it was so great that Dr Leslie determined to perform laparotomy. He opened the abdomen on the left side above my last incision. He wrote—

Imagine me a tomahawk of the abdomen on opening the peritoneal cavity there was a rush of gas and the abdomen went down by pushing my finger into the abdominal cavity would draw a loop of small and also of large intestine which appeared perfectly normal. There was no faecal colour about the escaping gas and the peritoneal cavity was as far as I was concerned perfectly aseptic. I left a small rubber drainage tube passing into the peritoneal cavity and did not make a colostomy.

Dr Leslie rightly remarks that the case is an extraordinary one. The gas must have come from the bowel from the lung or else have been formed in the peritoneal cavity itself. It was odourless and there was no peritonitis but this does not negative it being intestinal flatus. There had been no signs or symptoms indicating air from the lung, through the diaphragm into the peritoneal cavity. The spontaneous formation of gas in the cavity of the peritoneum is not unknown but it is only produced by gas forming organisms and peritonitis is invariably present. And the extreme distension of the intestines forced gas through their wall filtered it on its way and so allowed the collection of mucous gas in such considerable quantities as to cause great distension. The distension has been held in check ever since to date (September 1927)—that is for more than five months—by allowing the tube to remain in exit for the gas from the peritoneal cavity. I have detailed this case fully so that others who may have had similar cases may put them on record. For sure, I consider it to be probably one of congenital megacolon with osmosis or intestinal gas.

### Oxygen in the Peritoneal Cavity

Warmed septic oxygen gas has been introduced into the peritoneal cavity by means of a cannula passed obliquely through the abdominal wall. Introduced slowly and carefully it does not seem to cause discomfort or to be fraught with danger. A skingram taken after the inflation gases

## British Medical Association

## CLINICAL AND SCIENTIFIC PROCEEDINGS

## SOUTH WALES AND MONMOUTHSHIRE BRANCH

At a meeting of the South Wales and Monmouthshire Branch at the Swansea General Hospital, on November 17th Dr DAVID E. EVANS described two cases of renal infantilism.

*Renal Infantilism*

The clinical conditions were as follows:

The first patient was a girl aged 12 who on account of failing health had attended her school irregularly during the past six months. She now suffered from attacks of vomiting and periodic headaches. She was mentally of the average intelligence but physically stunted growth and thin. Her height was 50½ in (the average being 57 in) and her weight was 70 lb (average 81 lb). The striking feature of the condition was a marked bending of the long bones of the lower extremity producing a decided genu valgum. It was ascertained that she had attended much from unusual thirst and frequency of micturition for several years. The urine was pale, its specific gravity was 1022 and there was a faint trace of albumin present but no sugar, acetone or porphyrins were detected. The analysis of the urine generally indicated a polyuria due to renal diabetes rather than diabetes mellitus. The child steadily lost ground and died from uraemia in a few months after examination.

The second patient was a boy aged 13 who had been noticed by his parent not to be thriving. Although his appetite was good he was gradually losing weight, suffering from lassitude and on account of weakness he could not walk about. His spirit was always good. He was stated to be very thirsty and passed large quantities of urine would drink a pint to a pint and a half of water during the night and this polyuria and thirst had been noticed in his early childhood. At one period the condition was considered to be tubercular peritonitis and he remained under treatment at the St. Bride's Sanatorium for some time. Other children in the family had been strong and healthy and both parents were normal. The boy was small and thin, his weight was 62 lb (average 83 lb) and his height 49 in (average 53 in). There was general muscular wasting and he walked about with difficulty on account of a pronounced condition of knock-knee which had within the last few months become more marked. The head was rather enlarged but the heart and lungs were normal. The urine specific gravity was 1000, a dense haze of albumin was present and this showed the renal function to be very deficient.

Some six months after the examination Dr Evans had been asked to see a boy in the hospital who had recently had an operation for mastoiditis and who presented symptoms which could not be considered as arising from the disease or a post-operative condition. He recognized the patient as the boy previously described and did not doubt that the symptoms were those of uraemia from which the boy died in a few days. At the necropsy of the brain was found to be lightly oedematous with some exudate in the ventricle but there was no evidence of meningitis. The thymus and thyroid glands were not enlarged and the heart was found to be normal. An old peritonitis was observed. Both kidneys were very small firm and fibrotic with multiple small cysts in the cortical zone. Microscopic sections showed that the capsule was thickened and there was marked interstitial fibrosis with an area of active inflammation of interstitial tissue. The glomeruli were in varying stages of fibrosis and the tubules were very dilated in the non-fibrotic areas and lined with cubical epithelium throughout. The small arteries showed an endarteritis. The right suprarenal was normal but the left was not found.

Dr Evans stated that the condition was regarded by some as being due to fibrosis of the suprarenal glands. Renal infantilism was characterized by deformities of long bones of the rachitic type, a general rarefaction characteristic changes along the epiphyseal lines, liability to a deposit of poorly calcified bone under the periosteum and frequent split fracture running at right angles to the bone. There was marked retarded physical development and stunting of growth. These changes were associated with a chronic renal disease, especially in the form of interstitial fibrosis of the kidney which was possibly the result of some intra-uterine nephritis. These cases did not come under observation in the guise of a nephritis of any sort as a rule but as bone deformity in association with a remarkable stunting of growth the child appeared to be only half its true age. Both sexes were equally affected. There was no previous history of rickets or of parathyroid nephritis, and no evidence of syphilis as a factor. The kidneys were very small. The capsule was thickened and the surface was only slightly granular. The interstitial tissue was markedly increased and there were but slight changes in the parenchyma. The small vessels were

thickened, but there did not appear to be any other changes in the cardiovascular system or endocrine organs. The condition probably commenced in infancy. The patient was usually small from birth, but the special symptoms and deficient growth were not noticed until about the age of 6 or later. Thirst and polyuria might be early and marked. The joints were swollen, the knees and wrists being both affected. There was usually no bowing of the skull and genu valgum developed rapidly in the later stage of the disease. The quantity of urine varied, it may be very large with a low specific gravity. Albumin was present in a small amount and occasionally a few hyaline casts were seen. The physical development was markedly interfered with, growth was retarded and the patient was thin. Sexual infantilism occurred in some cases but not all. The intelligence was normal. Life had been prolonged in some cases almost to puberty but there was risk at any time of uraemia, as could be understood when the extremely small shrunk fibrosed kidneys were seen.

*Ophthalmic Cases*

Mr L. K. ROY THOMAS showed a man aged 24, who had been struck in the left eye by a rivet two days previously and had sustained a perforating wound, about 4 millimetres long at the upper and outer corneal scleral margin. Such an accident was very common especially in industrial districts. No foreign body was discovered within the globe. The patient was admitted to hospital, atropine was instilled and a padded bandage was applied. There was no ocular vision beyond perception of light. A traumatic cataract was present, with a swelling, lens and an anterior synechia. The eye was painful and tender and Mr Thomas said that it would require careful watching. It did not settle down soon, enucleation would be necessary in order to obviate sympathetic irritation of the right eye. Search would be made for keratitis punctata and blood counts be taken if these showed an excess of mononuclears the eye would be enucleated at once.

Mr Thomas also showed a case of embolism of a retinal artery in which an operation had been followed by recovery of sight. A man aged 53 while bending down to tie his bootlace suddenly lost the sight of his right eye. Two days later he showed the typical signs of embolism of a temporal branch of the retinal artery and an operation was immediately undertaken. Paracentesis of the corner with massage, was performed and an inhalation of amyl nitrite was given. The vision gradually improved from 0/36 to 6/9 partly with glasses and then to 6/6 fully with correction. The only defect which had persisted was scotoma corresponding to the small branch which was blocked. This did not interfere to any extent with the vision. Mr Thomas added that this case emphasized the necessity for immediate attention being given whenever sudden loss of vision occurred.

*Orthopaedic Cases*

Mr W. H. O. WOODS showed three orthopaedic cases.

The first patient was an achondroplastic dwarf aged 2½. The pathology of the disease was described and the point was emphasized that only bone laid down in cartilage was affected. A demonstration was given how this fact accounted for the deformities.

The second patient was a girl aged 12 who even years previously had suffered from attacks of swelling in the right arm which were accompanied by severe constitutional symptoms including prostration of 10½ to 16½ vomiting and great prostration. During the six years the attacks recurred but with decreasing severity. When Mr Thomas had first seen the child 3 years ago the arm was slightly swollen red and tender but there was no constitutional disturbance. The attack passing off in the course of a day. An interesting feature was that the arm from the shoulder downwards was of greater size than the other one the bones being ¼ in less long and proportionately larger than in left. The hand also shared in the hypertrophy. The whole limb resembling that of a girl aged 20. Mr Woods was unable to give a diagnosis but suggested that the condition had resulted from a local vascular or endocrine disturbance.

A series of plaster casts was exhibited to demonstrate the results of manipulation in a very rare case of congenital talipes equinovarus. The last cast showed that the foot was now in the normal position. The nature of the deformity was discussed and the attention was directed to its methodical correction. Importance was attached to the fact that the reduction of the deformity was only the first step towards cure, re-education was inevitable unless the treatment was continued until the child was able to walk, and complete muscular balance had been established.

very clearly the outlines of the solid abdominal viscera or of an intra-abdominal tumour. It is a method which may be given more trial in expert hands for cases of difficulty in diagnosis—as, for example, in the differentiation of a distended gall bladder from a right-sided mesenteric cyst. The oxygen gas is absorbed within twenty-four hours. It is well known that laparotomy, with or without subsequent drainage, has been of considerable therapeutic service in the serious variety of tuberculous peritonitis. What is the exact reason for the benefit which follows is still a matter of doubt, but some consider that the introduction of atmospheric oxygen may play a part. If this be so, might not the over-ventilation of a large proportion of fluid in tuberculous ascites and its replacement by pure warm aseptic oxygen have a similar remedial action?

#### Nitrogen in the Peritoneal Cavity

The formation of adhesions in the peritoneal cavity, either spontaneously or after laparotomy, is a very real matter, and may have serious consequences. Undoubtedly prophylaxis is of the utmost importance. The introduction of a harmless and not quickly absorbed gas into the peritoneal cavity might have a value in lessening the formation of adhesions. After a prolonged operation in which there has been considerable handling or stripping of peritoneum the whole of the incision might be closed except for a small space through which a fine catheter might be passed into the peritoneal cavity. Nitrogen, purified and warmed, may then be slowly introduced until a moderate distension of the cavity has been obtained, when the catheter should be withdrawn and a suture tied to close the abdomen. Very little if any discomfort results therefrom, even when the patient comes out from the effects of the anæsthetic.

### MEDICAL, SURGICAL, OBSTETRICAL.

#### ACUTE PHOSPHORUS POISONING

Acute phosphorus poisoning is rather rare nowadays, and the following details of a case which came under my care this year may, therefore, merit recording.

A married woman, aged 37, was admitted to hospital on September 7th with a history of having swallowed a teaspoonful of phosphorus mice paste two days previously. Within a quarter of an hour of taking the paste her stomach had been washed out and sulphur administered. The patient was said to have vomited several times after the washing out of the stomach. On admission to hospital she appeared rather nervous but answered questions quite sensibly. She said she had no pain anywhere but had belched wind several times. She asked for food but was only allowed water to drink since it was thought that milk might aid absorption of the phosphorus. There was no ulceration of the lips, tongue, buccal mucous membrane, or throat. The pulse was 60 and of good volume and tension; there was no hepatic enlargement, jaundice, or abdominal tenderness. Next day her physical and mental condition was apparently better and she was allowed tea and sugar and a piece of dry toast. There was no sign of enlargement of the liver and no jaundice. The pulse remained the same, and she had no pain or sickness. The food was returned. On September 10th she was drowsy, but not comatose. She resisted strongly attempts at palpation and percussion over the lower right costal margin. Slight jaundice of the skin and conjunctiva now appeared, and the liver could be felt by deep palpation under the right costal margin. Albumin and bile were found in the urine, but no leucine or tyrosine. A few granular and cellular casts with occasional polymorphonuclear leucocytes were seen and the urea percentage was 2. On the next day the patient was troubled with retching but did not vomit. The jaundice was more pronounced, especially in the conjunctivæ, and the lower edge of the liver was felt easily about an inch below the right costal margin. The patient appeared to be tender over this area, became restless on palpation though she lay quietly and did, except when being examined. The tongue was dry and was sore of the mouth but no petechial hæmorrhages of the tongue were observed. She became comatose and died on the morning of September 12th.

The autopsy report included the following details. There was

• The moderate seen on the surfaces of both lungs and their bronchovascular (10 oz. and 8½ oz.) into both pleural cavities. The pericardial in size, but showed some fatty degeneration. The pericardium was normal, but the cellular tissue in small quantities of the diaphragm, particularly over the right lobe extended to the level of the third

rib above, and below to about an inch below the right costal margin, and 2½ inches below the costal cartilage. The abdominal viscera small, very strongly of gelatinous. The spleen, which weighed 6½ oz., was deeply congested but there was no peritonitis. The left kidney weighed 6½ oz. and there were well marked hæmorrhages beneath the capsule and into the lower half of each pyramid, the capsule stripped readily. The right kidney weighed 5½ oz. and both organs showed fatty degeneration. There was no inflammation of the outer coats of the stomach. This vice contained a bluish brown glairy fluid resembling altered blood, which did not smell of phosphorus. Black specks, looking like altered blood, were studded over the inner coat, but these were not firmly adherent to the stomach wall. Hæmorrhages were seen on the surface of the pancreas. The uterus was non-gravid and appeared to have undergone some fatty degeneration. Hæmorrhages, each about the size of a split pea, studded the mesenteric surface. The bladder was distended, but the urine was not luminous in the dark, no naked eye pathological changes were found in the brain.

I am greatly obliged to Dr. Charles Gordon Lewis, resident medical officer, London Road Hospital, Newcastle, Staffs, for permission to publish particulars of this case.

C. F. SWINTON, M.B., Ch.B.

Newcastle-under-Lyme, Staffs.

#### ARTHRITIS DUE TO PARATYPHOID B BACILLUS WITHOUT GENERAL SYMPTOMS

A female child, aged 14 months, was brought to the outpatient department of the Belfast Hospital for Sick Children, with the following history.

About two weeks earlier the child's mother had noticed a disinclination to move the left leg, and that the knee joint was swollen. The child had previously been quite healthy, and there was no history of any infectious disease.

On admission the left knee joint was found to be swollen, and evidently contained a considerable quantity of fluid. It was not much inflamed. There were no other abnormal signs on general examination and the temperature was 98.8° F.

On the following day Mr. Hull explored the joint, and a thick, glairy exudate was withdrawn. From this fluid, which contained many pus cells, I was able to grow, in pure culture, a Gram-negative actively motile bacillus. On testing the sugar reactions of this organism I found it to agree exactly with the *Bacillus paratyphosus B*. I then made an agglutinable culture by Dreyer's method and obtained strong agglutination (up to 1 in 500) with standard *B. paratyphosus B* serum, and no agglutination with *B. paratyphosus A* nor *B. typhosus* serums. The serum of the patient also gave a strongly positive agglutination with standard *B. paratyphosus B* cultures (1 in 500), and no reaction with *B. typhosus* nor *B. paratyphosus A*. There were no general signs of paratyphoid infection. A rash did not appear nor was the spleen ever palpable, and the stools and urine both failed to show typhoid or paratyphoid organisms on culture.

The girl remained in hospital for eleven days. The temperature was normal throughout her stay, except on two evenings when it rose to 99.6° F.

The patient was taken home, but is now attending the outpatient department, and receiving an autogenous vaccine. There has been a gradual improvement, and at the end of one month's treatment the swelling has subsided and the joint is apparently normal.

I could obtain no history of infection in the family, but several cases of paratyphoid B fever have occurred in the district in which the patient lives.

J. T. LAWS, B.Sc., M.D., M.R.C.P. Lond.,  
Bacteriologist, Belfast Hospital for Sick Children.

#### SEVERE HÆMORRHAGE FOLLOWING VAGINAL TEAR

The following case is sufficiently unusual to merit record. A married woman, aged 28, ceased menstruating about 4 p.m. At midnight, immediately following coitus (the first attempt), she had a severe vaginal hæmorrhage, losing about three pints of blood. On my arrival the hæmorrhage had ceased, but she was suffering from very severe shock. I found it necessary to give her a subcutaneous infusion of saline, to which she responded well. The following day she was removed to hospital, where a more complete examination was made. A dense central adhesion was found between the anterior and posterior vaginal walls, leaving two small lateral apertures. This was situated about midway between the hymen and the vault of the vagina. A deep tear in the vaginal wall about 1½ inches long extended from the lateral aperture on the right side towards the hymen. The adhesion was broken down and the tear sutured. The patient made a good recovery.

## CLINICAL AND SCIENTIFIC PROCEEDINGS

## SOUTH WALLS AND MONMOUTHSHIRE BRANCH

At a meeting of the South Walls and Monmouthshire Branch at the Swansea General Hospital, on November 17th Dr DANIEL L. EVANS described two cases of renal infantilism.

*Renal Infantilism*

The clinical conditions were as follows:

The first patient was a girl aged 12 who on account of failing health had attended her school irregularly during the past six months. She now suffered from attacks of vomiting and periodic headache. She was mentally of the average intelligence but physically of stunted growth and thin. Her height was 50½ in (the average being 57 in) and her weight was 70 lb (average 81 lb). The striking feature of the condition was a marked bending of the long bone of the lower extremity producing a decided genu valgum. It was ascertained that she had suffered much from unusual thirst and frequency of micturition for several years. The urine was pale, its specific gravity was 1002 and there was a faint trace of albumin present but no sugar acetone or norals were detected. The analysis of the urine generally indicated a polyuria due to renal diabetes rather than diabetes in itself. The child steadily lost ground and died from uraemia in a few weeks after examination.

The second patient was a boy aged 13 who had been noticed by his parents not to be thriving. Although his appetite was good he was gradually losing weight suffering from lassitude and on account of weakness of the legs could not walk about. His spirits were always good. He was noted to be very thirsty, passed large quantities of urine, would drink a pint to a pint and a half of water during the night and thus polyuria and he had been noticed since early childhood. At one period the condition was considered to be tuberculous peritonitis and he remained under treatment at the St. Bride's Sanatorium for some time. Other children in the family had been strong and healthy and both parents were normal. The boy was small and thin, his weight was 62 lb (average 83 lb) and his height 49 in (average 53 in). There was general muscular wasting and he walked about with difficulty on account of a pronounced condition of knock-knee which had within the last few months become more marked. The head was rather enlarged but the heart and lungs were normal. The urine specific gravity was 1000, a decided haze of albumin was present and tests showed the renal function to be very deficient.

Some six months after this examination Dr Evans had been asked to see a boy in the hospital who had recently had an operation for malodour and who presented symptoms which could not be considered as arising from the disease or a post-operative condition. He recognized the patient as the boy previously described and did not doubt that the symptoms were those of uraemia from which the boy died in a few days. At the necropsy of the brain was found to be lightly oedematous with some exudate in the ventricles but there was no evidence of meningitis. The thymus and thyroid glands were not enlarged and the heart was found to be normal. An old pericentesis was observed. Both kidneys were very small, firm and fibrotic with multiple small cysts in the cortical zone. Microscopic sections showed that the capsule was thickened and there was marked interstitial fibrosis with an area of active inflammation of interstitial tissue. The glomeruli were in varying stages of fibrosis and the tubules were very dilated in the non-fibrotic area and lined with cubical epithelium throughout. The small arteries showed an endarteritis. The right suprarenal was normal but the left was not found.

Dr Evans stated that the condition was regarded by some as being due to fibrosis of the suprarenal glands. Renal infantilism was characterized by deformities of long bones of the rachitic type, a general rarefaction characteristic changes along the epiphyseal lines liability to a deposit or poorly calcified bone under the periosteum and frequent split fractures running at right angles to the bone. There was marked retarded physical development and stunting of growth. The changes were associated with a chronic renal disease especially in the form of interstitial fibrosis of the kidney which was possibly the result of some intrauterine nephritis. These cases did not come under observation in the guise of a nephritis or any sort as a rule but as a bone deformity in association with a remarkable stunting of growth in the child appeared to be only half its true age. Both sexes were equally affected. There was no previous history of rickets or of parathyroidous nephritis and no evidence of sepsis is a factor. The kidneys were very small. The capsule was thickened and the surface was only slightly granular. The interstitial tissue was markedly increased and there were but slight changes in the parenchyma. The small vessels were

thickened, but there did not appear to be any other changes in the cardiovascular system or endocrine organs. The condition probably commenced in infancy. The patient was usually small from birth, but the special symptoms and deficient growth were not noticed until about the age of 6 or later. Thirst and polyuria might be early and marked. The joints were swollen, the knee and wrists being both affected. There was usually no bowing of the skull and genu valgum developed rapidly in the later stage of the disease. The quantity of urine varied, it may be very large, with a low specific gravity. Albumin was present in a small amount and occasionally a few hyaline casts were seen. The physical development was markedly retarded with growth was retarded and the patient was thin. Sexual infantilism occurred in some cases but not all. The intelligence was normal. Life had been prolonged in some cases almost to puberty but there was risk at any time of uraemia, as could be understood when the extremely small, shrunk fibrotic kidneys were seen.

*Ophthalmic Cases*

Mr E. K. ROX THOMAS showed a man aged 24, who had been struck in the left eye by a rivet two days previously and had sustained a perforating wound, about 4 millimetres long, at the upper and outer corneoscleral margin. Such an accident was very common especially in industrial districts. No foreign body was discovered within the globe. The patient was admitted to hospital atropine was instilled and a padded bandage was applied. There was no ocular vision beyond perception of light. A traumatic cataract was present, with a swelling lens and an anterior synechia. The eye was painful and tender and Mr Thomas said that it would require careful watching. It did not settle down soon enucleation would be necessary in order to obviate sympathetic infection of the right eye. Search would be made for keratitis punctata and blood counts be taken if these showed an excess of mononuclears the eye would be enucleated at once.

Mr Thomas also showed a case of embolism of a retinal artery in which an operation had been followed by recovery of sight. A man aged 58 while bending down to tie his bootlace suddenly lost the sight of his right eye. Two days later he showed the typical signs of embolism of a temporal branch of the retinal artery and an operation was immediately undertaken. Paracentesis of the cornea with massage was performed and an inhalation of amyl nitrite was given. The vision gradually improved from 6/36 to 6/9, partly with glasses and then to 6/6 with correction. The only defect which had persisted was scotoma corresponding to the small branch which was blocked. This did not interfere to any extent with the vision. Mr Thomas added that this case emphasized the necessity for immediate attention being given whenever sudden loss of vision occurred.

*Orthopaedic Cases*

Mr W. H. O. WOODS showed three orthopaedic cases.

The first patient was an achondroplastic dwarf aged 2½. The pathology of the disease was described and the point was emphasized that only bone laid down in cartilage was affected. A demonstration was given how this fact accounted for the deformities.

The second patient was a girl aged 12 who even years previous had suffered from attacks of swelling in the right arm which were accompanied by severe constitutional symptoms including pyrexia of 101° to 104° vomiting and great prostration. During the preceding six years the attacks recurred but with decreasing severity. When Mr Thomas had first seen the child a year ago the arm was slightly swollen and tender but there was no constitutional disturbance. The attack passing off in the course of a day. An interesting feature was that the arm from the shoulder downwards was of greater size than the other, the bones being ¼ inch longer and proportionately larger. The child let the hand also hang in the hypertrophy. The whole limb resembling that of a girl aged 20. Mr Woods was unable to give a diagnosis but suggested that the condition had resulted from a local vasomotor disturbance.

A series of plaster casts was exhibited to demonstrate the results of manipulation in a very rare case of congenital talipes equinovarus. The last cast showed that the foot was now in the normal position. The nature of the deformity was demonstrated and the value emphasized in its methodical correction. Importance was attached to the fact that the reduction of the deformity was only the first step towards cure relapse was inevitable unless the treatment was continued until the child was able to walk and complete muscular balance had been established.

## Clinical Cases

Mr C L Isaac showed two patients

The first was a thin and pale man, aged 57, who had had a history of stomach trouble for the previous eighteen months, with pain which came on in hour after food. It was situated in the epigastrium, radiating round to the left side between the shoulders, and was relieved by food. There was occasional vomiting, but no haematemesis. The appetite was poor and the bowels regular. A mobile mass was palpable just above the umbilicus, and in x-ray examination showed a deformity of the pylorus in this region, with only slight delay in emptying. A fractional test meal indicated the presence of active secretion and normal neutralization which was compatible with an ulcer within the stomach. A partial gastrectomy was performed and a large mass was removed from the interior surface of the lesser curvature of the stomach, one and a half inches from the pylorus.

The second patient was a boy, aged 17, who had haematuria, with no other symptoms, and no previous illness. The patient was undeveloped, but there were no physical signs of disease in any organ. The urine contained a large number of blood cells, leucocytes, and tubercle bacilli. A culture was sterile. A renal efficiency test showed blood urea 37 mg per cent, uric acid, 185 mgms and the haemoglobin index 1.50. No x-ray evidence of calculi in the urinary tract was obtained and the bladder was normal, apart from a red patch round the left ureteric orifice. Methylene blue came through the right, but not the left, ureter. Nephrectomy of the left kidney was performed and the specimen was exhibited.

A woman, aged 47, had had stomach trouble for four years, x-ray examination showed hour glass contraction to be present, with a penetrating ulcer at the lesser curvature in the cardiac portion. A fractional test meal showed that the gastric secretion was hyperactive neutralization was delayed there was hyperacidity, and evidence of pyloric delay probably due to spasm. The analysis was characteristic of duodenal ulcer but in operation brought to light a gastric ulcer together with hour glass contraction. Partial gastrectomy was performed and the jejunum was anastomosed to the stomach. The ulcer was found to be of the benign type, with much fibrosis in the muscle layers and an inflammatory reaction in a small adjacent lymphatic gland, no evidence of malignancy was obtained.

The fourth patient was a man, aged 50, with a history of absolute obstruction of four days duration with vomiting, distension, pain shortly after food and constipation for four months. He had lost weight during the last few months, but there was no blood in the stools. Laparotomy was performed and the small intestine was found to be distended with fecal fluid in the abdomen. An irreducible ilio-colic intussusception was discovered and a thickened caecum. The tumour was excised the opening in the ascending colon was closed and the end of the ileum was united with the transverse colon. Section of the tumour showed it to be an adenocarcinoma with a mixed inflammatory reaction and congestion. After six years the patient was still alive, well, and at work.

Dr Iwan Davies exhibited skiagrams illustrating bilateral renal calculi, in organic hour-glass stomach, with a penetrating ulcer on the lesser curvature in ulcer of the posterior wall of the body of the stomach, a seven months' foetus in utero, with extended breech presentation, two cases of tuberculosis of the spine, involving respectively the first, second, and third lumbar vertebrae, fracture of pelvic ring showing union in good position, fracture of the neck of the femur, and loose bodies in the knee-joint.

## STAFFORDSHIRE BRANCH

A GENERAL meeting of the Staffordshire Branch was held at the North Staffordshire Royal Infirmary, Stoke-on-Trent, on November 24th.

## Injuries to the Eye

Mr R H DICKSON read a paper entitled "Injuries to the eye in their medico-legal aspects." He specified the occupations in which injury to the eye was liable to occur, and dealt with the types of trauma most commonly met with. He discussed the pathology and the appropriate treatment of the particular types of case coming within the category of the paper, and considered in detail important points relating to sympathetic ophthalmia. The bearing of medical evidence on claims relating to compensation was fully explained, and the present state of court procedure in such cases was described and illustrated by examples. Mr Dickson put in a plea for the modification of the present procedure by the transference of judicial function, so far as the hearing of medical evidence was concerned, to a board of medical assessors, who would be much better able to sift medical evidence than a judge no matter how clear minded and erudite he might be.

## Suppurative Tenosynovitis

Mr ERIC YOUNG in a communication on "Suppurative tenosynovitis of the palm," described in detail the anatomy of the flexor tendon sheaths and of the various cellular and fatty tissue of the hand.

hand which were liable to suppuration. He next considered the diagnosis of the presence of pus in different situations, and indicated the best lines for operative intervention. He showed the exact sites which should be selected in making incisions, and particularly emphasized the point that in involvement of the common flexor tendon sheath proximal to the transverse carpal ligament the main mass of pus was invariably behind the tendons, lying between them and the pronator quadratus. He added that a collection of pus in this situation should not be incised from the front through the tendons, the approach should be made from the side in the plane of the potential space between the tendons and the pronator quadratus.

## Endoscopy

Mr G A CARTER described some uses of endoscopy, and showed a large number of instruments for the examination of the passages and oesophagus. He discussed the symptoms, aetiology and pathology of conditions causing difficulty in swallowing, and accounted a variety of cases which had come within his personal experience. He mentioned foreign bodies impacted at different points in the antrum and gullet, and demonstrated methods for their removal, together with a large number of specimens which he had extracted from different sites.

## Heart block

Dr A WILSON GILL read a paper entitled "Auriculo-ventricular bundle branch block and its diagnosis by the electrocardiogram." Dr Gill explained the anatomy and physiology of the nodal and auriculo-ventricular bundle system of the heart, and described the waves seen in cardiographic tracings of the normal heart. He then discussed the pathology and symptomatology of bundle branch block, and demonstrated cardiograms of the condition. He showed that in this disease there was a definite and pathognomonic derangement of the QRS complex, the QS time interval was increased, there were secondary oscillations on the upstroke and downstroke of the wave, and the point of the wave frequently exhibited a notch or bifurcation.

## Reports of Societies.

## LATE RESULTS OF OPERATION FOR CARCINOMA OF THE BREAST

REPORT BY A COMMITTEE OF THE MEDICAL SOCIETY OF LONDON

At the meeting of the Medical Society of London on November 28th, Mr HERBERT W CURSON in the chair, the report of a committee appointed to investigate the late-results of operations for cancer of the breast was presented and discussed. The committee, which was appointed in July, 1923, consisted of Sir James Berry, Mr Warren Low, Mr Percy Sugent, Mr Herbert Curson, and Mr T P Legg. The discussion of the report is printed at page 1085.

## A STUDY OF 265 PATIENTS ALIVE AT LEAST TEN YEARS AFTER OPERATION

The scope of the inquiry was limited to the tracing and investigation of patients for whom the primary operation was performed not less than ten years previously, and an inquiry form, sent to Fellows of the Medical Society and to surgeons attached to various hospitals in the British Isles, elicited 320 replies, 265 of these were accepted as coming within the scope of the inquiry, and form the basis of the report. The reasons for selecting patients who survived more than ten years after operation were (1) To establish a time period after which recurrence was likely to be infrequent, (2) to give a broader survey to the question of permanent freedom from recurrence, (3) to adopt a more satisfactory time period than the three- and five-year periods hitherto adopted in statistical investigations. The committee considered the three-year period too short, while the five-year period appeared to be that in which recurrences were most likely to occur. On the other hand, fifteen years appeared to be too long, because most patients "drop out" at the end of that period, would have long extended to the end of the period, and its metastasis towards the hymen. The committee sought to determine any common the tear sutured. The account for long survival should be taken into account for long survival.

The data collected have been analysed and tabulated by Mr W. I. Turner.

**SEX**—All the patients were females with the exception of three; the incidence of cancer of the breast in males being about 1 per cent. The evidence does not support the theory that the prognosis is worse in males; the three were alive and free from recurrence after eleven, fifteen, and eighteen years respectively.

**MARRIED OR SINGLE AT DATE OF OPERATION**—The percentage of single women is slightly higher than that given in the literature and the evidence shows that the prognosis is slightly better in the single than the married. The figures are: married (2 male) 60.4 per cent; single 23.3 per cent; widows 71.1 per cent; not stated (1 male) 4.1 per cent.

**AGE AT TIME OF OPERATION**—The prognosis in young patients is shown to be not so bad as is generally supposed while the decennium 40 to 50 years has the best prognosis. A considerable drop in the percentage of survivals occurs after 50 years of age but allowing for the normal expectancy of life after 60 the prognosis of cancer of the breast would appear to be good. The percentages of survivals for different ages at the time of operation are as follows: 21-30 years 1.5 per cent; 31-40 14.7 per cent; 41-50 44.1 per cent; 51-60 23.8 per cent; 61-70 9.4 per cent; 71-80 2.3 per cent; not stated 4.1 per cent.

**CHILDREN BEFORE OPERATION AND BREAST-FED CHILDREN**—There were 143 married women and 19 widows making a total of 177. Of these 22 were childless; none of the single women had born children. The number of children and the method of feeding were not stated in 45 cases. Of the remaining parous women in all the children were breast-fed in 25 it is not known whether the children were or were not suckled in 14 the children were not breast-fed. In 3 women it is definitely stated that the affected breast was not used for suckling. In 4 cases carcinoma abscess developed in the breast subsequent to affected by carcinoma. There were 7 cases of septic mastitis in breast which were affected later with carcinoma. In one of these it was noted that the carcinoma developed twenty years later in the indurated area around an incision scar. No instance of carcinoma arising in an actively lactating breast occurs in the series.

**BREAST AFFECTED AND POSITION OF GROWTH IN BREAST**—In 43.3 per cent the growth was in the right breast; in 49.1 in the left and in 2.6 the side is not stated. There is thus no evidence that the side affected has any influence on the prognosis. With regard to the position of the growth in the breast the report gives tables showing the number of cases in which respectively the whole breast, all four quadrants, the individual quadrants, the nipple and the axilla were primarily affected and the right and left breasts are separately considered. A separate table shows the results when the two breasts are considered together. The upper half of the breast was involved in 32.6 per cent; the lower half in 16.5 per cent; the outer half in 32.3 per cent; the inner half in 10.5 per cent; and the central part in 8.1 per cent. In four cases the greater part of the breast was affected and in two no tumour was found in the breast but secondary deposits were present in the axillary glands.

#### OPERATIONS AFTER MERELY NAKED-EYE DIAGNOSIS

Of 23 patients on whom the radical operation was performed 19 were alive and well for periods varying from ten to twenty-three years after the primary operation. One was alive with intrathoracic growth eighteen years after operation but without local recurrence. Two died from local recurrence fifteen and twelve years respectively after the primary operation; one died with recurrence in the supraclavicular glands secondary to a recurrence in the pleura ten years after the primary operation. Among the patients in this group two had enlarged axillary glands and both were alive and well seventeen and thirteen years respectively after the radical operation. In one patient radium was applied to a recurrent nodule one year after operation; the nodule disappeared and the patient was well twelve years after the primary operation. In one case a recurrent nodule in the skin over the lumbar spine was excised three years after the primary operation and the patient was well thirteen years after the primary operation. Of two patients whose axillary glands were infected at the time of the primary operation one was alive and well thirteen years later; the other had a portion of the fourth costal cartilage and part of the pericardium excised seven years after the primary operation and the patient died from local recurrence twelve years after the primary operation. In one patient the supraclavicular

glands were excised one year after the primary operation, and the patient was alive and well sixteen years after the original operation.

In a second group of nine cases in which the diagnosis was made on naked-eye appearances alone the primary operation was "incomplete." In two cases of local excision of the tumour there was in one case a massive recurrence in the breast and the axillary and supraclavicular glands were enlarged. A radical operation with excision of the supraclavicular glands was performed and the patient was well, with no signs of recurrence sixteen years after the primary operation. In the other case a radical operation was done one year after the primary operation; the patient was alive twelve years after the first operation with recurrence in the car and secondary deposits in the spine. In a patient in whom the axillary glands were enlarged the breast, pectoral and axillary fasciae and axillary glands were excised and she was well with no signs of recurrence sixteen years later and in a similar case but without enlargement of the glands the patient was well twenty-three years afterwards. In three patients the breast and axillary glands were excised; one was alive with recurrence in the scar fourteen years after the operation; in the second recurrent nodules in the scar were treated with x-rays three years later; the nodules disappeared and the patient was well with no signs of recurrence ten years after the primary operation; in the third a nodule in the scar was excised two years after the primary operation and the patient was alive and well fourteen years after. In three patients the breast only was excised, and subsequently each had operations for local recurrent nodules. In one the axilla was cleared two years after the primary operation and two other operations were done for local recurrences in the scar four and seven years later—he was well and without recurrence eleven years after the primary operation; in the second case three operations for local removal of recurrent nodules were performed and the patient died with recurrence eleven years after the primary operation; the third patient had two or three operations for local recurrences in the first two years after the primary operation and one for recurrence in the pectorals major fifteen years later when a ray treatment was instituted; the patient dying thirty-two years after the primary operation from peritonitis.

#### OPERATIONS AFTER ALLEGED MICROSCOPICAL DIAGNOSIS

In 19 cases the diagnosis is stated to have been made by the microscopical appearance but these were not described in detail and no macroscopical appearance of the tumours were given. A radical operation was done in 8 cases; in one the supraclavicular glands were excised for recurrence ten years after the operation and the patient died twelve months later from recurrence; in another the opposite breast was removed for carcinoma six months later. Seven patients were well with no signs of recurrence ten to eighteen years after the primary operation. In 5 cases the operation was performed in stages; in one the radical operation was done soon after the excision of the axillary glands, the patient being well, with no signs of recurrence ten years after the primary operation; in four others a local excision of the tumour was followed by a radical operation at intervals varying from five days to two months, 2 of the patients being well with no signs of recurrence ten years after the primary operation and 2 twelve years after. In one case a supposed adenoma and a year later local nodules of carcinoma were excised, followed by a radical operation; the patient being well with no signs of recurrence nineteen years after the primary operation. In 3 patients the breast only was excised; in one there were operations for local recurrence—eight and fifteen years after the primary operation; the patient dying from cancer shortly after the last operation; in another a local recurrence was excised and the supraclavicular glands removed six years after the primary operation; the patient being well and free from recurrence twenty-one years after the primary operation; in the third a dissection of the glands at the neck on the same side, with removal of a cancerous gland under the mastoid, was made nine months after the primary operation; removed

by excision of the axillary glands eleven years after the operation, the patient being alive, with local recurrences, twelve years after the primary operation

#### OPERATIONS AFTER DEFINITE MICROSCOPICAL AND MICROSCOPICAL DIAGNOSIS

##### *Histological Types*

In 212 patients the diagnosis was confirmed both microscopically and metacoscopically. In 45 of these the tumour is described as a spheroidal-cell carcinoma with much fibrous tissue (*scirrhous carcinoma*). A radical operation was performed in 40 of these, and 31 were alive and well, and free from recurrence, ten to twenty years after the primary operation, 4 died from causes other than recurrence, with no sign of cancer, one was alive, with recurrence in the supraclavicular region, ten years after the primary operation, 4 died from recurrence. In one patient the breast, fascia, and superficial fibres of the pectoralis major were removed and the axilla was not touched, this patient died of recurrence in the chest wall eighteen years after the primary operation. In another the breast, fascia, superficial fibres of the pectoralis major, and the axillary glands were removed, and the patient was alive and free from recurrence twenty-seven years after the primary operation. In two patients the breast, pectoral, and axillary fascia and glands were excised, they were alive and free from recurrence ten and twenty years respectively after the primary operation. An incomplete primary operation in two cases was followed by death with recurrence in eleven and fourteen years respectively.

In 26 patients the tumour is described as a *spheroidal-cell carcinoma*. A radical operation was done in 21 of these, of whom 19 were well and free from recurrence for ten to sixteen years after the primary operation. One died from heart disease at the age of 64, sixteen years after the primary operation, another was alive with supraclavicular recurrence ten years after the primary operation. In 5 patients the breast, fascia, and axillary glands were excised at the primary operation, all of these were alive and free from recurrence from eleven to nineteen years after the operation.

In 4 cases the growth is described as an *adenocarcinoma* (a variety of spheroidal-cell carcinoma). A radical operation was done in all, and they were alive and free from recurrence eleven, fourteen, fourteen, and fifteen years after operation.

In 11 cases the growth is described as *encephaloid*. In all a radical operation was performed, and all were alive and free from recurrence ten to twenty-three years after the primary operation.

There were 12 cases of *duct carcinoma*. A radical operation was done in 11 of these, all of whom were alive from eleven to sixteen years after operation, and free from recurrence. In one case local excision with a little of the surrounding breast tissue was done, and the patient was alive and free from recurrence fifteen years later.

In 4 cases the growth exhibited *mucoid change*. A radical operation was performed in all, 3 were alive and free from recurrence eleven, fourteen, and seventeen years respectively after the primary operation, one was alive twelve years after operation, with local recurrence.

One patient had an *atypical growth*, with preneoplastic changes in the ducts and malignant secondary glands. A radical operation was performed and, six years later, Wertheim's operation for carcinoma of the cervix, the patient was alive, with no signs of cancer, ten years after the primary operation.

#### SCORE OF OPERATION AS REGARDS BREAST, MUSCLES, AND GLANDS

*Local Excision of Tumour at Primary Operation*—Of the 15 cases in which this operation was performed 14 had a radical operation within a few days or months of the local excision. The patient in whom no second operation was performed (a case of duct carcinoma) was well and free from recurrence fifteen years after operation. Of the remaining cases, 13 were well for periods of ten to thirty-four years after the primary operation, two of these were operated on for carcinoma of the other breast. One case was alive with recurrence in the scar and secondary

deposits in the spine twelve years after the primary operation.

*Breast only Excised at Primary Operation*—This operation was done in 12 cases. In two nothing further was done, one of these was alive and free from recurrence twenty-four years later, and had had a colostomy for carcinoma of the rectum performed twenty years after the breast operation, the other died twenty-five years after operation with extensive local and glandular recurrence. The remaining ten patients had secondary operations, varying in scope. 5 of these were well, with no signs of recurrence, 3 eleven years, one twenty-one years, and one twenty-six years after the primary operation, one was alive, with recurrence in the axillary glands, fourteen years after the primary operation, 3 died from recurrence eleven, twelve, and thirteen years after the primary operation, one died of peritonitis, with no sign of recurrence, thirty-two years after the primary operation.

*Axillary Glands Excised at Primary Operation*—In two patients no growth was found in the breast. The axillary glands were culled, removed, and found to contain carcinoma. A radical operation was done a few days later, and the patients were alive and well eleven and ten years later.

*Breast and Axillary Glands Removed*—In 7 of the 14 patients there was no subsequent operation, 3 of them were well and free from recurrence twenty-one, eleven, and twenty years later, 2 were alive, with local recurrence, twelve and fourteen years later, 2 died from recurrence eleven and fourteen years later. Seven other patients had subsequent operations—two for carcinoma of the other breast, 5 for local recurrent nodules, and one for recurrence in the supraclavicular glands. Three were well twelve, ten, and fourteen years after the primary operation, one was alive with recurrence in the supraclavicular glands fourteen years after, and 3 died of recurrence fourteen, twenty-four, and fourteen years after the primary operation.

*Breast, Pectoral and Axillary Glands and Fascia Excised*—There were 21 patients. In 15 no subsequent operations were performed, 14 of these were well, with no signs of recurrence, ten to twenty-three years after operation, one died, free from recurrence, of old age (80), one had keloid scars removed and was well after eighteen years, one had an operation for carcinoma of the other breast, and was well ten years after the primary operation. Four patients had secondary operations for recurrence, one was well sixteen years after the primary operation, two were alive, with recurrence, twenty-four and twelve years after, one died from bronchitis twenty years after the primary operation.

*Breast, Fascia, Part of Pectoralis Major, but no Glands, Excised*—One patient, two operations for recurrence, death from recurrence in chest wall eighteen years after the primary operation.

*Breast, Fascia, Pectoralis Major, and Axillary Glands Removed*—There were 44 cases. Of these 34 were alive and well ten to twenty-three years after operation, 3 were alive, with recurrence, ten, eighteen, and eleven years after operation, 2 died ten and nineteen years after operation, with no signs of recurrence, 5 died, with recurrence, ten to eighteen years after operation. There was a secondary operation for recurrence in 7 patients, and in one the other breast was removed for carcinoma.

*Breast, Fascia, Pectoralis Major, Pectoralis Minor (Divided or Removed), and Axillary Glands Excised*—There were 135 cases, of whom 121 were alive and well ten to twenty-two years after operation, 4 were alive, with recurrence, ten to twelve years after operation, 5 died of recurrence ten to eighteen years after operation, and 5 died from causes other than cancer, and with no signs of recurrence, eleven to sixteen years after operation.

*Pectoralis Major, Fascia, Axillary, and Supraclavicular Glands Removed*—There were 11 cases, in none of which were the supraclavicular glands infiltrated with cancer. In none were there secondary operations for recurrence, but one patient had colostomy performed for carcinoma of the pelvic colon. Ten were alive with no signs of recurrence eleven to fourteen years after the primary operation. One was alive with metastases in the liver and peritoneum thirteen years after operation.

The report next deals with the method of doing the operation, and the subsequent operations which became necessary. In nearly 25 per cent of the total number of patients one or more operations were necessary in addition to the primary operation. Details of these are tabulated, under the headings of (1) Recurrence in skin or parts adjacent to operation area, (2) Recurrence in glands of the same side as the breast operated on, (3) Recurrence in the pleura, (4) Recurrence in the skin over the lumbar spine, and (5) Supposed recurrences proved not to be malignant on microscopic examination.

#### CARCINOMA IN THE OPPOSITE BREAST

In 13 patients carcinoma developed in the opposite breast. The growths do not appear to have been recurrences except possibly in 3 patients in each of whom operations had been done for local recurrences on the side of the primary operation. In most cases a number of years elapsed between the operations on the two breasts. Of the 13 patients 3 died—one from bronchitis twenty years after the primary operation and six years after removal of a malignant ovarian tumor. The other 2 died from recurrence twelve and thirteen years respectively after the primary operation, the other breast having been removed two years before death. Nine patients were alive with no signs of recurrence one to five years after the operation on the second breast and one patient lived for thirteen years.

Very little information was gained with regard to treatment by x rays and radium. X rays were employed in 44 cases and radium in 8 full details of which are given in the table. Several tables deal with the subject of glandular infiltration and its effect on prognosis after operation.

#### SUMMARY OF LATE RESULTS OF OPERATION

Of the 265 patients 73.6 per cent were alive and well with no signs of recurrence at intervals of ten to thirty-four years after the primary operation. 3.8 per cent were alive and well at intervals of ten to twenty-six years after the primary operation but had undergone an operation for carcinoma of the other breast—in one of these more than ten years had elapsed since the second operation in the other 9 the interval was less. 1.5 per cent had operations for carcinoma in other parts of the body. 3.8 per cent were alive and well at periods of ten to twenty-one years after the primary operation but had had one or more operations for recurrence. 7.9 per cent died with recurrence more than ten years after the primary operation at intervals of ten to twenty-five years. 3.8 per cent died more than ten years after operation at intervals of ten to thirty-two years without signs of recurrence.

Of the patients who were alive more than ten years after the primary operation recurrence appeared in 46 (17.35 per cent). These cases fall into two groups: (1) Ten were alive with no signs of cancer but had had an operation for recurrences which were with one exception all local to the primary operation. (2) Fifteen were alive with signs of recurrence and 21 died of recurrence more than ten years after the primary operation. Taking the two groups together the recurrences were local in 25 patients in 17 of these they appeared within ten years in 6 between ten and fifteen years and in 2 between twenty and twenty-five years. The critical times after operation would appear to be the first three years (13 patients—28 per cent—had recurrences in these years) between nine and ten years (when there were 10 cases of recurrence—22 per cent) and again between ten and fourteen years when recurrence occurred in 11 patients—24 per cent.

#### PRESENT POSITION

Of the 265 cases dealt with in the report 195 patients are alive and well with no sign of recurrence (after ten years 21 patients, after eleven 23, after twelve 22, after thirteen 26, after fourteen 22, after fifteen 18, after sixteen 9, after seventeen 11, after eighteen 8).

after nineteen 1, after twenty 7, after twenty-one 2, after twenty-two 2, after twenty-three 3, after twenty-four 1, and after twenty-five 1. Ten patients are alive and well but within the last ten years have had an operation on the other breast for carcinoma. Four patients are alive but have had an operation for carcinoma in some other organ. Ten patients are alive and well, but have had an operation for local recurrence. Fifteen patients are alive but with local recurrence. Twenty-one patients died with recurrence more than ten years after the primary operation. Ten patients died more than ten years after the primary operation from causes other than carcinoma and with no signs of recurrence.

#### DISCUSSION

Mr. J. P. IEGG, a member of the committee, after summarizing the conclusions of the report dealt with two general criticisms. One was that it was not known of how many patients the 265 accepted cases, which formed the basis of the report were the survivors. On the criterion of some figures supplied from their own practices by Mr. Grey Turner and Mr. Hey Groves it would appear that the 265 might be said to be the survivors of between 1,900 and 2,500 individuals. The second criticism was that the information being supplied by a large number of surgeons there was great diversity in terminology and in other more important respects this was certainly a weakness of the statistical method. Very little information was to be gained from the report as to the use or value of radiation methods, awaited an answer. In one respect the report was disappointing. It had been hoped that some common factor might be found which would account for long survival. That hope had not been realized.

Mr. HERBERT CAPSON said that it was a matter of great regret to the committee that no common factor which made it impossible to give a term to the chance of recurrence in cases of cancer of the breast success had attended the treatment of local recurrences.

Mr. W. E. MILES speaking from an experience of treatment of cancer of the breast extending back for twenty-eight years emphasized the need of keeping in view not merely extrathoracic but also intrathoracic spread and the possibility after extensive operation of the breast of metastases in the supraclavicular glands. For the purpose of more complete removal of the affected supraclavicular glands he had removed the clavicle thereby obtaining an excellent exposure. He regarded the surgical treatment of cancer of the breast as largely fortuitous. If the operation had included the whole of the tissues which had been invaded by the extension of cancer cells from the primary focus then it was a success but if the cancer cells had passed beyond the scope of the operation into the thorax it was a different matter. He had never seen at the Cancer Hospital a case of cancer of the breast cured by x rays. For a time, after breast excision he had sent cases for exposure to x rays with the idea that any isolated cancer cells might thereby be destroyed but he had never seen such early rapid and widespread recurrences as in the cases he dealt with the whole area exposed to x rays seemed afterwards full of minute metastases.

Mr. W. SAMUEL HANDLEY said that an unreasoning pessimism on the part of the public was one of the difficulties of the surgeon. Patients with a lump in the breast had an idea that if it was not cancer there was no hope and if it was cancer there was no hope. Among his own private patients the average time which elapsed between the patient first noticing something wrong and coming for medical advice was nearly six months. The uncertainty or a tentative inquiry in such a complex matter as breast cancer was limited. His own view was that a detailed study of a series of individual cases was likely to be more fruitful than a study of a large number. There was a general tendency to despair of a case if recurrence followed the operation and the present report would serve as a corrective. The discrepancy between the descriptions quoted in the

report seemed to point to the necessity of obtaining a standard collection of histological specimens, and also of encouraging a supply of competent histologists by providing appointments which would permit able men to devote their whole career to histology.

Mr T P WATSON said that since 1919 he had had at his disposal a very satisfactory follow-up department, and on dividing his cases into two groups, those before and those after the institution of this department, some interesting comparisons were made possible. The number of lost cases, which figured largely in the earlier returns, was greatly diminished as a consequence of the follow-up system. In a group of 93 cases operated on, it appeared that 17 had had recurrences within less than one year, 12 in from one to two years, 9 in from two to three years, and 2 in from three to four years, the greatest number of recurrences were found before the end of the second year. Of the other patients, 40 were well, one had died from another cause, and three were untraced, a-ray treatment had proved of great value in cases of recurrences.

Mr JOSEPH SWAN gave figures obtained from an inquiry at the Cancer Hospital in 1924 as to the cases which had been treated during the period 1904-14. Of 562 operated on, 433 were known to be dead, 45 were alive and well at the time of the inquiry, and 84 were untraceable. The analysis of the figures bore out the point that the earlier a case was obtained the better were the chances of a good result. He agreed with Mr Miles as to the ineffectiveness of x-rays. He had never seen a case of cancer of the breast cured by x-rays, though he had seen several cases of simple subcutaneous recurrence clear up.

Dr S WARD took exception to one statement in the report, because, although it expressed what was literally true, it left an inference which he believed to be negated by the facts. It was stated that "Looking at this table [a table giving the number and date of recurrences in 46 patients] a striking feature is the small number—4 patients (8.6 per cent)—with recurrence after fourteen years." The inference was that the longer the patient lived after operation the less was the likelihood of recurrence. Thus, he believed, could not be sustained.

Mr DUNCAN BIRZEWILLIAMS said that a considerable number of patients mentioned in the report had a local operation, and then, at a later stage, perhaps two years afterwards, a radical operation, if the condition was not generalized then a local operation would cure it. He was thinking of those breasts in which an operation was performed for some suspicious symptom, and enormous was found afterwards, not the cases of manifest malignancy. There were such cases in which a local operation was sufficient. He had not found x-rays very effective, but he had a great respect for radium, which rendered inoperable cases not only operable, but so nearly normal that he had sometimes refused to operate. Radium, however, had the most deleterious effect when associated with the operation, for it delayed healing and sometimes caused a burn.

Mr WALTER LOW said that the committee, of which he was a member, chose the period of ten years, because it was felt that there would be little use in taking a shorter period. One of the impressive things brought out in the report was the large number of survivors, many of them free from recurrence, ten years after operation. It was evident that if surgery could not cure these cases it could delay the ultimate end for a number of years.

Mr ZICHARY COPE raised the question as to what was the natural history of cancer. How many patients survived without operation at all? It seemed that cancer might be either long-lived or short-lived, some cases lasted for years, in others the spread was so quick that the patients died in a year or less. Cancer lay dormant over such extraordinarily long periods that it seemed doubtful whether it could ever be said to be cured.

Mr DONALD ARMOUR, speaking with regard to x-ray treatment, said that the West London Hospital was the first to apply the bilugene treatment to carcinoma of the breast, but no cases could be written off as either cured or improved by that method. With regard to the mode of spread there was no doubt in his mind that in many cases in which the supraclavicular glands had become

infected, the infection was not from the axillary glands but from the intrathoracic glands.

Mr W E TAYLOR, who had analysed and tabulated the results, replied briefly to appreciative remarks by Mr LIGA and Mr CARSON.

## DIAGNOSIS OF SURGICAL DISEASES OF THE KIDNEY

At a meeting of the Royal Medical-Chirurgical Society of Glasgow, on November 18th, the president, Dr JOHN COWAN, in the chair, Mr ROY YOUNG opened a discussion on modern views regarding the diagnosis of surgical diseases of the kidney.

Mr Young described the routine examination of a patient with suspected urinary trouble. This comprised a complete report of the history of the illness, thorough examination of the patient, including the blood pressure, chemical, microscopic, and bacteriological tests of the urine, and a record of the amount passed in twenty-four hours, radiological examination of the urinary tract, and an estimation of the total renal efficiency, which in some cases could be omitted. At the first cystoscopy the whole bladder was examined with special reference to the appearance of the ureter orifices and the rate and character of the efflux from them, the colour test was also performed. A second examination might be necessary, with catheterization of the ureters, in order to collect the separate urines, for location of stone, or for pyelography. The obvious drawback to such an examination was that it involved expenditure of time and money. Mr Young thought that the examination should stop at the point where it was concluded that an accurate diagnosis had been made. This might occur early in the examination or not until the final pyelograph. He illustrated the necessity of a complete examination of the whole urinary tract by the case of a man who had been under treatment for a considerable time for nephritis, since albumin had been found in his urine. No benefit followed, and then a bacteriological examination of the urine revealed the presence of coliform bacilli. He was treated with vaccine and, after a time, seemed to be cured. He went away for a holiday, but on the second day he had to be admitted to hospital, where a large phosphatic calculus was removed from the bladder. On his return to Glasgow, since he appeared to be no better, he came into the Western Infirmary, where Mr Young removed a very large calculus, together with a functionless pyonephrotic right kidney.

Mr ARTHUR H JACOBS confined his remarks to the diagnosis of renal infection—the commonest of all surgical diseases of the kidney. In pyelitis this was confined to the renal pelvis and calyces, in pyelonephritis the perinephrium, or kidney proper, was also involved while in a pyonephrosis there was gross distention of the kidney substance, which might result in the organ being converted into a mere bag of pus. The symptoms of renal infections might be exhibited in a fulminating, acute, or chronic form, but in all types the urine contained organisms and pus, the latter varying in quantity from a few cells to a thick deposit easily recognized by the naked eye. Frequent and sometimes painful micturition, occasionally accompanied by a dull ache or pain in the loins, were the usual urological symptoms. In the majority of cases the pyuria was chronic, and an attempt was made to find out the source of the infection, whether one kidney or both were involved, to what extent the renal function had been impaired and the kidney substance destroyed, whether any complication such as ptosis, calculus, or hydronephrosis was present which would tend to keep the infection persisting or predispose to its recurrence. Only after these questions had been answered could a rational line of treatment be adopted. In about 80 per cent of cases the causative organism was *B. coli* communis, in the less common staphylococcal and streptococcal infections evidence of recent or old septic foci might be found on the cutaneous or mucous surfaces. After a preliminary x-ray examination of the complete urinary tract to exclude calculus all areas of the bladder were examined cystoscopically to exclude the presence of any vesical papilloma or diverticulum.

Mr J SCOTLER BUCHANAN thought that since the diagnosis and localization of stone was possible in most cases by the ordinary physical and radiographic means patients

being inserted towards the lower pole of the kidney. This so-called abnormal vessel often tended to constrict the uretero-pelvic junction and was thus a fruitful cause of hydronephrosis. The symptoms arising from this condition were those of hydronephrosis, and in ache in the back, generally without minor disturbance, was the outstanding feature. These, taken in conjunction with a negative finding on x-ray examination, suggested the advisability of pyelography, which would at once give a perfect demonstration of the cause, the picture generally showed kinking and constriction at the pelvic outlet. It had been questioned whether mobile kidney ever caused kinking of the ureter and obstruction to the free outflow of urine, but the symptoms in many of these cases were identical with those caused by stone or any other condition which might obstruct the outflow of urine from the kidney. A negative result from x-ray examination indicated the necessity of making a full urinary investigation. Pyelography in such cases would not only determine the cause of the pain, but the nature of the treatment required to relieve it. Ectopic kidney, though comparatively rare, had been mistaken for tuberculous disease of the caecum, and in operation showed only a non-inflammatory retroperitoneal tumour suggestive of kidney. Pyelography proved the truth of the supposition, and further showed that the mass consisted not of one but of two kidneys, fused, and of the horseshoe type. The ureters in this case proceeded to the mass from normally situated bladder openings. It had been estimated that one in about every two thousand four hundred persons had only one kidney, a fact which should be remembered by the surgeon performing a nephrectomy, and more especially where sepsis was present and the loin incision was used. It should be a rule never to remove a kidney without previously having made certain of the presence of a second, and put it from opening the abdominal cavity—a proceeding not without danger in the presence of sepsis—the only method was pyelography. Cystoscopy showing the normal excretion of indigo carmine from a normally placed ureter might be fallacious. Horseshoe kidney, the presence of double ureters, double kidney, and various other developmental defects were all conditions which in most instances should be recognized before and not at operation.

Mr. JAMES R. LEWIS considered that employment of the modern diagnostic methods required is given attention to surgical ritual is did any other operation. In uninfected cases freedom from chills and fever after the examination might be taken as in index of the attainment of surgical cleanliness, it was practically certain that these resulted from temporary bacteriemia. That the number of such reactions could be reduced to a very low figure was shown in a recent series of five hundred pyelographies, in which only seven patients had pyrexia above 100° F. Given that the surgical technique could be made impeccable the cystoscope was definitely contraindicated (1) when the patient was aged and infirm, (2) when he was greatly weakened, (3) when bilateral renal impairment of an extreme degree was present as detected by clinical data, studies of the blood chemistry, and renal efficiency tests, (4) when it was apparent that no surgical procedure could be of any benefit. Under the first three conditions even the mild ordeal of cystoscopy might turn the scale against the patient, and suppression of urine might occur. As an example of the fourth contraindication might be cited the hypothetical case of a patient who had haematuria, a mass in the loin, and a pathological fracture of a long bone. In introducing the cystoscope various anatomical difficulties might be encountered, thus phimosis, an unusually narrow meatus, or a urethral stricture might require correction. If dilatation of a stricture was necessary the cystoscope could be passed it was probably such a defer cystoscopy for a few days. In prostatic whether or not marked intraventricular projection might offer

Mr. DON, the passage of the instrument. Inspection treatment, stone might solve the urinary problem, and first to apply to our passage of ureteral catheters was briefest, but no case had circumstances in which it was or improved by these the ureters were the presence spread, there was no time not accounted for by the cases in which the urethra, the need of detection of each kidney the necessity

of making a pyelogram, and the necessity for identifying a ureteral stone. Certain precautions might be taken to guard against the possibility of conveying infection to a non-infected kidney by the passage of a ureteral catheter through an infected or tuberculous bladder. The previous exhibition of urinary antiseptics helped to reduce the infection, the bladder must be well washed out before the cystoscope was introduced, and in certain types of instrument the ureteral catheter might be introduced and passed while continuous irrigation was provided through the cystoscope. When these precautions were taken the risk of infecting the kidney was very slight. There might be considerable mitomical difficulty in finding the ureteric orifices and introducing the catheters. Thus the ureters might enter the bladder at abnormal positions, the presence of a cystocele might distort the vesical picture, and in infected bladders, especially when the infection was tuberculous, seeping from cystitis and metritis might impede the passage of the catheter, or might even prevent the identification of the ureteral orifice. In the latter case it might be necessary to expose one or both ureters in the loin, as described by Fullerton, in order to discover the state of the kidneys. Pyelography should not be attempted when a diagnosis could be reached without it, as, for example, in hydronephrosis, by obtaining a large amount of residual urine from the kidney pelvis, in the aged, infirm, or emaciated, and in acute infection of the kidney. Pyelograms might be made on both sides at the same time, should it seem desirable. The solution employed for pyelography was non-irritating, non-toxic, easily sterilized, almost neutral in reaction, and flowed in and out of the pelvis as easily as water. Its only disadvantage was that it was not germicidal. Too much solution must not be introduced. The patient was conscious, and was thus able to complain of the pain to which over-distension gave rise, although if the catheter had been pushed so far in that its eye rested in a calyx he might complain of pain after the introduction of enough fluid to distend the calyx alone. In practice this error was easily recognized and rectified by withdrawing the catheter an inch or so. Then, again, the calibre of the ureteral catheter should be such that any excess of fluid could escape down the ureter. Fluid introduced at too high a pressure was apt to find its way into the intrarenal venous system, such a possibility ruled out pyelography in acute kidney infections. After the radiogram had been taken the fluid was removed from the renal pelvis with a syringe before the catheter was withdrawn. The interpretation of the pyelogram was often beset with difficulties. There were so many variations in the shape of the normal pelvis and calyces that a considerable amount of experience was required before it could be definitely said that the pyelogram was abnormal, and the appearance must always be considered in the light of the clinical data.

## DEEP X-RAY AND RADIUM THERAPY IN RELATION TO THE UPPER RESPIRATORY TRACT

At a meeting of the Section of Laryngology of the Royal Society of Medicine on December 2nd, Mr. HAROLD BIRWELL presiding, a discussion took place on deep x-ray and radium therapy in growths of the mouth and upper respiratory tract. It was preceded by the exhibition of a number of specimens and cases, and members of the Section had an opportunity earlier in the day of visiting the throat and the radiotherapeutic departments at St. Bartholomew's.

Dr. W. L. WATT described the applications of x-rays of extreme hardness, filtered through copper or zinc, in the treatment of growths, and pointed out the differences between deep therapy of the upper respiratory tract and that of the uterus. The uterus he compared to an island, it was completely surrounded by fluids, and gave opportunity for that wide action of the rays which was particularly desirable in order to inhibit and destroy the disease. But should the same principles of application be employed in the irradiation of the larynx, where one had, not an island at all, but a surface covered on part all covered with an, general overdosage would be extremely likely to

Mr. Stevenson Case thought that lesions of the roof and  
back of the mouth responded better to radiation than  
those of the floor. Tumours of the palate could be made  
to disappear in nearly every case by means of radium. For  
treatment the mouth must be clean and nearly all the

The President result had been thoroughness. The President said that he had been greatly impressed with what he had seen at St. Bartholomew's that morning—the work of Mr. F. A. Roe, Mr. Douglas Harmer and Dr. Finzi. He might quote one remark made by Mr. Harmer—namely that if he saw a case of malignant disease too far advanced for laryngeal surgery but suitable for laryngotomy he considered it should have radiotherapy first but if it was suitable for laryngeal surgery he was rather in doubt as to what operation he would take up. That the President thought would be the general view.

Mr Dunhill declared that the administration of an-  
thetis to patients suffering from the various forms of  
goitre called for great ability on the part of the sur-  
geon. Mechanical difficulties were encountered in ca-  
ses of bilateral colloid goitre and in intrathoracic goitres in  
addition to which there were complications such as tachy-  
cardia. These patients had often unclean mouths and  
enlarged tonsils. A quiet urethra was essential since  
otherwise a second operation might be necessary to re-  
move the chloroform from the gland. Mr Dunhill had at first  
hesitated to use adrenaline until it had been exophthalmic  
but it was positively contraindicated. On rare occasions

it was the anæsthetic of choice, and was best administered by the single drop method. In most cases requiring a general anæsthetic ether had replaced chloroform. The method of choice was the intratracheal, since it enabled a sterile field of operation to be maintained and ensured a smooth anæsthesia. The rectal method of administration was useful at times, since the head of the table was freed from apparatus. A light degree of narcosis was required and not full surgical anæsthesia; the dose should be calculated on the side of under dosage. It could be supplemented if necessary by inhalation of ether, or gas and oxygen. Nitrous oxide with oxygen was valuable and might be combined with local anæsthesia. The latter was unsuitable for young or frightened patients, but it had the advantage of securing a bloodless field, for its proper exhibition there must be mutual co-operation between patient and surgeon. For adenoma endotrachealis and oxygen with possibly a little ether was indicated in most cases. In a dry examination it is essential to determine the position and shape of the trachea; no anæsthetist should be expected to pass an intratracheal catheter until this had been done. For colloid goitres general anæsthesia with ether was advisable, preferably by endotracheal methods. Gas and oxygen could be used except in patients suffering from great mental stress. In exophthalmic cases chloroform was contraindicated, and probably ether was the most satisfactory anæsthetic. Out of 700 operation cases he had used local anæsthesia in 403, and general anæsthesia in 292, in 5 cases he had been unable to trace the anæsthetic used.

Dr JAMES BLAIR said that he preferred open ether by the drop method with a very light depth of anæsthesia. In cases with dyspnoea, cyanosis, and defective cardiac condition local anæsthesia was the most satisfactory form, and this was also the case with exophthalmic goitres. Dr Z. MARRAS used the question of the value of preliminary medication in goitre cases. Dr J. BLOMFIELD thought that an undesirable depth of anæsthesia might be required in order to pass the intratracheal catheter. Dr G. I. MONTAGNA believed that the anæsthetic was more dangerous than the operation. Lady BENN preferred the open ether method with the minimum of anæsthesia, so that patients were in a state bordering on consciousness and talking. She denied that ether was an unpleasant drug for induction when given slowly, dyspnoeic cases often improved under this anæsthetic, the action of the heart being regularized where it had been disordered before induction. Dr L. HILTON condemned the practice of anæsthetizing nervous patients in bed and then moving them on a trolley to the theatre, such a proceeding was dangerous in goitre cases. In toxic cases with fibrillation local anæsthesia alone should be used. In his experience hot vapours were more irritating than cold, and so should be avoided in goitre cases. Dr C. F. HADFIELD agreed as to the irritating qualities of warmed anæsthetic vapours, but Dr F. T. EVANS disagreed, he believed that by warming the vapour it was possible to ensure an even flow of properly vaporized anæsthetic. Moreover, the temperature of such a vapour, when it reached the patient's mouth, was very little above room temperature, if the warming chamber was not placed too close to the mouth.

Mr. DUNN, in reply, said that he certainly believed in the efficacy of preliminary medication, which was especially beneficial in operations under local anæsthesia. He advocated scopolamine and morphine in these cases, and he preferred morphine to amorphine or piriton. For injection he used novocain of a strength of one quarter of 1 per cent. He did not think that a great depth of anæsthesia was essential for the passage of an intratracheal catheter. He had not observed much hæmorrhage follow the use of local injections in goitre cases.

### TECHNIQUE IN TROPICAL DISEASES

At a meeting of the Section of Tropical Diseases and Parasitology of the Royal Society of Medicine on December 1st, the President of the Section, Professor R. T. LEWIS, F.R.S., in the chair, a number of papers on recent advances in technique were read.

Dr H. H. SCOTT described his method of estimating the

amount of ionic calcium in the blood serum for the diagnosis of spina, and for determining the progress of the patient. In the blood plasma, calcium was present in the ionic form, free or diffusible (6 to 6.5 mg per 100 c.c.), and in the combined or non-diffusible form (4 to 4.5 mg). On clotting of the blood all the calcium became ionic, and so in the serum the amount of ionic calcium represented the total calcium. In spina serum, however, although the total calcium was about normal, the ionic was much diminished, being sometimes as low as 6.3 mg in a severe case, the remainder being combined. With convalescence this figure gradually rose until, when the patient had recovered, the figure was again normal. From an experience of many hundred cases Dr Scott had found that this remained true for spina only. The test had three stages. To graded quantities of ammonium oxalate were added in series fixed amounts of fresh blood, the tubes were incubated for ten minutes at 37°C, and the highest dilution with absence of clotting was noted. A series of tubes were put up with this dilution, fresh blood was added together with fixed amounts of graded calcium chloride, in this way the smallest amount of calcium causing complete clotting was determined. The first series was repeated, using the patient's serum instead of the calcium, and by a simple calculation the calcium content could be found. In normal serum there was 10 to 11 mg of ionic calcium, in severe spina only 6.3, in a mild case 7.8 to 8.2, while in a cured case the figures of 10 to 11 were again found.

Dr P. MINSON-BURN discussed technique as applied to clinical diagnosis, referring among other methods to serum tests for trypanosomes, agglutination methods on microscopic slides, the intradermal test for undulant fever, and the use of the sigmoidoscope in diagnosis of the various forms of dysentery. By this last test scrapings of the mucosa could be made, and cultures might often enable a diagnosis between the amoebic and the bacillary forms.

Dr J. GORDON THOMSON discussed protozoological technique, and drew attention to the necessity for an accurate knowledge of the use of the microscope. All the intestinal protozoa could be readily diagnosed in a faecal film preparation if the illumination was properly arranged. He also referred to methods of culture of these forms, all of which, except *Giardia*, could now be successfully cultivated in artificial media.

Dr W. NICOLL considered the methods by which helminth infections could be diagnosed by means of faecal preparations and blood smears, the various clinical methods of diagnosis in use, including the intradermal tests for hydatid and similar conditions, the methods of collecting helminth parasites, and their preservation.

Dr V. B. WIGGLESWORTH, who dealt with entomological technique, described methods of rearing in the laboratory blood sucking bugs, such as those which transmitted South American trypanosomes.

Dr J. BROUGHTON ALCOCK, in discussing bacteriological technique, gave details of the "slide agglutination" tests for various bacteria—especially those of the typhoid group. Drops of emulsions of the organisms to be tested were laid along one edge of a slide and opposite each was placed a drop of the suspected serum. By tilting the slide each drop of organism was made to mingle with the corresponding drop of serum. Dr Alcock had found that the mixture which first showed agglutination was the cause of the infection. He also drew attention to cytological methods of distinguishing between amoebic and bacillary dysentery. In the first condition degeneration was purely from without, in the latter it was from within. In the tropics, chicken-pox could be distinguished from small-pox by means of Jennerian vaccination, if the suspected condition was small-pox the vaccination would not "take."

Mr. RANSBROUGH dealt with mycology from the medical point of view, and said that morphology was the first stage in the diagnosis of the microfungi. All groups could not be cultured on an artificial medium, and cultures were best examined in distilled water or in lactophenol. In many cases morphology alone was insufficient, and certain physical, biochemical, and pathological tests were necessary also in addition to normal sporulation and life history.

Many fungi such as ringworm were phormorphic but this was often not seen in the standard media in which pathological fungi were generally known. A large number of different media should be used in order to obtain the perfect form. As a rule only the imperfect form had been seen in the pathological types. A thorough knowledge of general and plant mycology was essential before the study of the more difficult forms could be successfully undertaken.

Dr J. F. C. HASTAM, in discussing the technique of hygiene, said that this subject ranged over the entire field of human life, the most difficult part of it perhaps was to deal successfully with colleagues, more especially in the tropics. He drew attention to the many kinds of problems in this sphere—drainage, housing, water, latrines, and general sanitation. He illustrated his remarks by lantern slides of tropical conditions.

Dr ANNA BALFOUR reviewed the whole subject and proposed a vote of thanks to the speakers.

In closing the meeting the PRESIDENT announced that a laboratory meeting would be held at the London School of Hygiene and Tropical Medicine on January 5th, 1928 at 8.15 p.m. at which the various speakers would demonstrate the several forms of technique to which they had referred in their evening.

### SPLENIC ENLARGEMENT

At a meeting of the Devon and Exeter Medico-Chirurgical Society held at the Royal Devon and Exeter Hospital on November 27th Mr A. L. CANDLER (in the chair) showed two patients with splenic enlargement.

Mr Candler said that the first patient, a woman aged 31 had been confined on October 9th 1927 and was admitted to hospital on October 21st with a ruptured perineum and puerperal fever. She was in a condition of protracted anaemia. The temperature was 101° on admission and the pulse 136. Owing to foul smelling lochia the uterus was cleared out and colloidal iodine given. On November 5th there was further rise of temperature and a large tumour was found to project from the left costal margin and extend to the midline. A blood count showed haemoglobin 5 per cent, colour index 0.75, red blood cells 3,020,000 per cmm, leucocytes 2,600, differential count—polymorphonuclear 6 per cent, lymphocytes 33 per cent, large mononuclear 6 per cent and eosinophils nil.

The second patient was a woman aged 49 with Banti's disease. Frequent haematemesis had been the only complaint and had occurred on five occasions during twelve years. He had brought up five pints of blood in October 1927. The liver and spleen were enlarged and the blood count was: red blood cells 4,600,000 per cmm, haemoglobin 70 per cent, colour index 0.8, and white cells 5,000, polymorphonuclear 62 per cent, small lymphocytes 32 per cent, large lymphocytes 5 per cent, and eosinophils 1 per cent. No abnormal cells were seen. Since 1925 she had been given iron and arsenic internally and had had three treatments with x-rays. It had been decided to perform splenectomy.

Dr W. GORDON, discussing the two cases alluded to Banti's disease as splenic anaemia which had set up hepatic cirrhosis and ascites. The operation mortality for splenic anaemia was 12.5 per cent, and for Banti's disease (which had progressed to ascites) 50 per cent. In the case of Banti's disease splenectomy had been indicated before the meeting, in view of the severe haemorrhages. Dr Gordon considered that splenectomy was the only treatment for splenic anaemia and in his opinion the earlier it was performed the better it was for the patient. As regards relief of the symptoms in Banti's disease splenectomy was usually successful in patients who survived the actual operation. Other treatment could only be regarded as palliative.

### Carcinomatous Metastases in Bones

Dr Gordon read notes on the x-ray appearances of secondary cancer in bones in a case of carcinoma of the prostate. He said that the photographs shown illustrated admirably the features of secondary cancer in bones. The history of the case practically indicated the diagnosis which had been established by rectal examination and the skinograms. It was regrettable that there had been no x-rays. The patient, aged 62, was in his usual health until October, 1926, when he began to have pain in his right thigh. In the following January he had to take to bed where the pain became less severe but about a month later pain commenced in the left thigh and the lower part of his back became stiff. He could not move his pelvis in

bed without great suffering, he lost flesh and grew weak. A fortnight before admission while making some ordinary movement against moderate resistance with his right arm he fractured the humerus near the shoulder. Such a history indicated the need of a rectal examination, and the prostate was found to be hard, small and irregular, there was no growth of the bowel wall, and no bladder symptoms. In May cancer with bone metastases was diagnosed and the patient was sent into hospital for a radiological examination. He had no spinal disease. The x-ray pictures showed fracture of the neck of the humerus with surrounding bone changes. There were similar metastases throughout the right side of the pelvis and some in the left pubic region. The patient was kept comfortable with morphine till his death in September. Dr Gordon said that there were four primary cancers specially prone to metastasize in bone, these were carcinoma of breast, prostate, and thyroid, and in children certain medullary hypernephromata. The last named affected the skull the others involved the skeletal bones selecting the proximal long bones in the limbs. In the prostate cases the first symptoms calling attention to the disease were often those due to the bone deposits.

### Clinical Cases

Dr HUGO showed a man aged 56 with diaphragmatic hernia which had been accidentally discovered during a routine examination for an ulcer of the nose. It was found that the heart was displaced to the right and x-ray examination revealed that the stomach and splenic flexure of the colon were in the thorax. It was thought probable that there was a large congenital defect in the left lat of the diaphragm. The man had worked hard as a farmer and beyond light shortness of breath made no complaints which could be referred to the malposition.

Mr NORMAN LOCK showed an infant aged 6 weeks, on whom he had operated at the age of 3 weeks for meningomyelocele. The protrusion was dissected and completely removed. Paralysis of the rectum now existed but the bladder functioned normally. Mr Lock remarked that hydrocephalus was liable to follow at a later age—3 to 5 years. Mr LOCK also showed a boy aged 4½ with rheumatoid arthritis, who had been admitted to hospital last February with limitation of movement in the left hip and knee joints, effusion into the left knee-joint and some apparent thickening of the tissues round the right hip joint. The boy was put up in a plaster cast so as to include the pelvis, the left knee and the right thigh and leg. In June it was noted that there was spontaneous contraction of the muscles round both elbow joints on active or passive movement. No information was derived from x-ray examination in June and no improvement had seemed to follow the wearing of the appliance. In September a long-chain streptococcus was cultivated from the throat and vaccines so derived were given. In November a further x-ray in extension revealed an enlargement rather knobby in character in the region of both elbow joints. Ultra-violet rays had been tried but attention was now being devoted chiefly to the prevention of deformities. Massage had been considered harmful as being likely to set up irritation of muscles. Dr W. GORBOY said that these cases came under the classification of Still's disease and tended to improve in time.

Dr DYBALL, in association with Dr CARROLL, showed a woman aged 60 with lumps in the skin of the breast resembling blind boils which were indurated round the bases and exuded a purulent-like fluid on squeezing. No glands had been noted in the axilla. The case had improved slightly with timentations. Mr DYBALL considered that this might be an unusual variety of Paget's disease, the nodules being away from and not involving the nipple. He had referred the case for x-ray treatment since in his opinion there was too extensive involvement of skin or justify excision. Dr R. V. SOLLY, who had cut sections of the growth and carcinoma was not quite reconciled to the description of the disease since the classical carcinoma growing from the ducts.

Mr A. L. CANDLER showed a man with a lump in the groin. There was a history of the excision of a similar lump on the same side in 1916 and also about eighteen months ago. Mr Candler asked for the opinion of the meeting on the diagnosis. Mr DYBALL said he had seen a similar case where the diagnosis proved to be spindle-celled sarcoma.

### Pathological Exhibits

Dr R. V. SOLLY showed four specimens. The first came from a case of alcoholic cirrhosis of the liver in a man aged 53 who was an old drinker and a consistently excessive fat drinker. There was severe haematemesis on admission to hospital. The necropsy disclosed very marked cirrhosis of liver (typical lobular) and slight ascites. The veins of the stomach were much dilated. The second was a case of syphilitic cirrhosis of liver in a man aged 42, with two months' history of ascites. The patient gradually became comatose and died from hepatic coma. There was a positive Wassermann reaction. The necropsy revealed an irregular cirrhosis, mainly of the lobular type with areas of excessive fibrosis. The spleen was also enlarged. The third was a case of diverticulitis with perforation in a man aged 63 who gave a history of three to four months' constipation and intestinal colic. He was subsequently treated with sudden severe

abdominal pain and rigidity, and died during transport to the hospital. At the necropsy free gas was found in the abdomen, and the intestines were suddenly inflamed, and covered with flakes of lymph. There were several inflamed and indurated diverticula of the pelvic colon, on opening the bowel one of these showed ulceration with perforation into the general peritoneal cavity. The fourth specimen was the heart of a pig, showing endocarditis, obtained from a case of infection with swine erysipelas, there were large vegetations in the region of the tricuspid ventricular valves.

Mr B. DYALL showed a case of chronic intussusception of the jejunum, where, during operation, it was found that the duodenum was larger than the colon. The whole mass was resected, and recovery had been uneventful. Dr. Gordon stated that he had seen the patient two months prior to the operation with symptoms of gastric ulcer, although suggesting the possibility of the possibility of gastric ulcer. No tumour could then be detected in the abdomen.

Mr A. L. CAYLER showed a "strawberry gall bladder" removed from a woman in whom colotomy had previously been performed for obstructive symptoms relative to diverticulitis of the lower sigmoid. During the past year there had been abdominal pain, frequent vomiting and loss of weight. Although she was tender over the gall bladder, there had been no attacks of biliary colic. Adhesions were found at the operation.

### TREATMENT OF LUPUS

At the meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland, held on October 28th, Dr. E. T. FRANKLIN showed a cured case of lupus vulgaris, and another of lupus erythematosus. In the first patient, a woman aged 35, the duration of the lupus vulgaris was not definitely known, but it had been present for at least twenty-one years. It occupied the left parotid region, and extended forward from the angle of the jaw to nearly the mid line of the neck. It was crusted and verrucous over the parotid, and of the dry non-ulcerative type on the neck. The treatment had consisted of light baths three times a week with carbon arc lamps, and galvanocautery every three weeks, to pick out individual nodules. The patient was now practically cured. The scar was fine, supple, and very slightly noticeable. The patient had been under treatment since June, 1926. The second patient was a woman, aged 34, who had had lupus erythematosus for many years. In the February issue of the *Lancet* of *Dermatology* Jay F. Achmberg, who had had considerable experience with other gold compounds, had reported 25 cases, mostly still under treatment, with smoothism. These were the first cases in which this drug had been used in lupus erythematosus. In April last Dr. Freeman had started treating two patients, one of whom had failed to continue attendance, and the patient now shown was the other. She had received seven intravenous injections of 0.10 gram each, at weekly intervals. There had been an immediate and steady improvement with entire disappearance of the lesion in seven weeks. The white atrophic scar always left by lupus erythematosus could be well seen. Dr. Freeman believed that this was the first case of this condition treated by this drug in Great Britain or Ireland, and the result had been perfect. There had been no reactions from the injection, and no local treatment had been used. He did not wish to over-emphasize the deductions from a single case, but the other patient had been doing equally well, and no other treatment, external or internal, had ever given him a comparable result. The President said that in neither case was the scar noticeable. He thought that the doses of smoothism in the second case had been very small, to be so efficient, and it was interesting to notice that the patient had had no reaction or discomfort after treatment. Dr. MURDER DRUMMOND thought that the result in the first case had been very good, considering the extremely delicate work which the galvanocautery required. The reason that such cure was essential in its use was the danger of leaving scars. The disadvantage of treatment by the carbon arc lamp was the length of time required. He suggested the possibility of the use of x rays, galvanocautery, and ultra-violet rays in treating these cases, the x rays being applied locally, and the ultra-violet rays generally. Dr. W. G. HARVEY, referring to the effect of x rays on cases of lupus, said that elsewhere he thought then use was regarded as almost criminal. If applied badly, they could do much harm, but, if properly treated, cases of lupus improved wonderfully

after their application. Lupus erythematosus was exceedingly hard to cure. He did not agree with the belief sometimes expressed that lupus erythematosus was a tuberculous disease, and he hoped that the result of treatment by smoothism would not be quoted in support of that belief.

### CHANGES IN OBSTETRICAL PROCEDURES

At a meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland on November 4th the President, Dr. GIBSON FITZGIBBON, took the chair and delivered an address on some points in obstetrics calling for reconsideration and possibly revision.

Dr. FitzGibbon first referred to the increased frequency with which Caesarian section was performed for contracted pelvis without there being a corresponding reduction in the number of craniotomies and difficult forceps deliveries, or any considerable improvement in the mortality of the mothers and infants. He advocated antenatal clinics strongly, and he looked forward to such a development as holding out the only hope of improvement in the future. He considered in detail the various conditions of expectant mothers which could be dealt with by antenatal supervision, early treatment in such cases would lessen the need for operative midwifery.

Dr. L. CASSIDY did not agree that diet had such an important bearing on the presence of albuminuria, which occurred in 85 per cent of the cases. He thought that 2 grams protein showed a really severe condition of kidney disease, and that the strain thrown on the kidneys in even a perfectly normal pregnancy was fairly great. In the treatment of contracted pelvis Caesarian section must be regarded as a failure of obstetrics, the number of women who required it at term was comparatively small. If every woman was carefully examined at the thirty-sixth week of pregnancy he thought the mortality from Caesarian section would be reduced almost to vanishing point. The operation should be attended with very little risk to the patient, 30 per cent of all women had the head unfixed at the onset of labour, and yet a fairly large percentage of the women would have a perfectly normal labour. Every woman at the thirty-sixth week in whom the foetal head could not be forced into the pelvis should be examined under anaesthesia in order to find out why the head could not get into the pelvis.

Dr. BRUNN SOLOMONS, the Master of the Rotunda, said that he had increased the scope of antenatal supervision in the Rotunda very largely. He thought that private practitioners should charge a composite fee for attendance, in order to encourage patients to attend regularly, and where patients were attended on the panel system antenatal supervision should be paid for and should be compulsory. The incidence of Caesarian section had become greater and the operation had been abused. In spite of every effort to avoid it, the number of cases at the Rotunda had increased, but the operation was performed nearly always after a trial of labour, and the lower segment was the site of choice, the operation in this neighbourhood could not be regarded as a failure in obstetrics, and in cases which, after careful antenatal supervision, a thorough trial of labour combined with pelvicmetry, terminated in a live mother and child, the end result might be regarded as good obstetrics.

Dr. WILLIAM SMITH agreed that toxemia was provoked by superabundance of feeding. He did not think that enough Caesarian section operations were performed in cases of placenta previa, and in Germany the operation was now frequently used in cases of eclampsia. Regarding the question, "How long should labour be tried?" he thought that this resolved itself into a matter of experience. The head would remain above the brim till the cervix was retracted. If the cervix was not drawn up within three or four days he did not believe that many obstetricians would wait much longer.

Dr. J. S. QUINN said that Caesarian section was a way of getting out of a difficult case, but he believed that all obstetricians wished to avoid performing the operation unnecessarily. He thought that the operation had not

been used enough in the peculiar cases which occurred occasionally. The results obtained from it were poor, and not on a par with the results of any other major operation in surgery for a non-malignant condition. The maternal mortality was large and there was at least 50 per cent. sterility after the operation. He thought that diet had some bearing on albuminuria, for he had noticed while at the Rotunda Hospital that the patients who had the worst albuminuria were of the well-to-do artisan class, who would get plenty of food.

Dr A. H. Davidson considered ante-natal work the most important advance in obstetrics within recent years. It brought a large number of women with abnormal pregnancies into hospital. He quoted statistics of a maternity welfare association in Detroit which indicated that the mortality of cases delivered in that city was 6.75 per 1,000, and the mortality of those delivered in the clinic was 3.5 per 1,000. The deaths from puerperal sepsis in the city were also much higher than in the clinics. The maternal mortality had been reduced by over one-half but the mortality from eclampsia had only been reduced by 25 per cent. 30 per cent of the women who attended the ante-natal clinics were found to have some intercurrent disease or abnormality which in the majority of cases could be set right. Only 6 per cent of the women of Detroit, however, came to the clinics. Ante-natal care should be continued as post-natal care.

Dr A. P. Burns had found that the urine of almost every pregnant woman contained albumin, and he thought that the only way to arrive at a conclusion about albuminuria was to obtain a satisfactory specimen.

Dr R. H. Conder, returning to ante-natal care, said that the chief difficulty now was the inertia of the people, it thus could be overcome he felt that a great advance would be made. The increase in Caesarean section and eclampsia was due in some measure to the increased transport facilities; many cases were sent up to town which some years ago would have been treated in the country.

The President in his reply stated that he did not condemn operative midwifery in the hospitals but he thought that the cases ought to diminish. Any patient who showed abnormality at ante-natal clinics should then be put under special care. Regarding trial of labour, he said that in some cases seven or eight hours was long enough but in others it was not. After trial of labour he at once favoured lower segment section, though at one time he had performed the classical segment section. The important thing in the management of obstetrical cases was to watch them all through. The question of diet and its relation to albuminuria should be investigated by the aid of ante-natal supervision as it was well worth while going into. In England the maternity hospitals did not practice internal pelvimetry. The picking out at ante-natal clinics of patients who were going to have abnormal labours and persuading them to go into hospital, would reduce the maternal mortality.

### ABERDEEN MEDICO CHIRURGICAL SOCIETY

A clinical meeting of the Aberdeen Medico-Chirurgical Society was held on November 3rd. The President, Dr J. I. Cammiste, in the chair. Dr L. Stewart Sandeman showed a case of aneurysm of the ascending aorta in a woman aged 50. There was definite bulging of the chest wall to the right of the sternum about the level of the second rib. The left vocal cord was abducted and the left radial pulse was hardly perceptible. The Wassermann reaction was positive. A skiagram showed the aneurysm very clearly. Under treatment with weak tincture of iodine three times a day there had been marked diminution of the dyspnoea and the patient felt better. Dr J. C. Macle showed a girl aged 7 years with calcinosis and widespread calcareous deposits in the subcutaneous tissues. She was given iodides for three months with no improvement and it was only after treatment with doses of sodium phosphate that the deposits began to disappear rapidly. Mr I. K. Smith brought a patient for diagnosis. A woman aged 55 had complained of tingling and altered sensation in the left forearm and hand for six

weeks. She had noticed a swelling in the left side of the neck for four weeks. Before the tingling came on she had had several attacks of bronchitis. On examination a hard irregular mass was felt at the root of the neck; it was immovable and definitely fixed to the deeper structures. It was not tender on pressure and there was no difficulty in swallowing the mass remaining stationary during the act. There was a well-defined semicircular area of dullness over the left apical region, with diminished breath sounds and vocal resonance, but no signs of fluid. An x-ray examination revealed a tumour mass occupying the upper part of the left lung and extending into the neck. The Wassermann reaction was negative. Dr A. G. Anderson showed a man, aged 49, who had been sent to him one and a half years previously, on account of a thrombosis of one of the left retinal veins. He weighed 17 st and had a blood pressure of 210 mm Hg. Under diet limiting the carbohydrate element and small doses of thyroid extract each day the blood pressure came to 145 mm of mercury and the patient lost 4 st in weight. He was now able to resume his work as a police sergeant. The point of interest in this case was the presence of a very high blood pressure and a retinal thrombosis both of which seemed to indicate a bad prognosis but under the treatment described a remarkable improvement had taken place. Mr G. H. Coit showed a man, aged 62, who had had an extensive epithelioma removed from the region of the right anterior pillar of the larynx five months before the neck glands had also been removed. A recurrence of the disease was evident and the advisability of further treatment either by diathermy or radium was contraindicated. Dr Robert Richards showed a specimen of urine from a patient who had had a small burn dressed with 1 per cent picric acid solution. The urine had been in his consulting room for several months without decomposing; it smelt strongly of phenol and the patient was at the time acutely ill with the signs of picric acid poisoning. The question of idiosyncrasy was fully discussed; the interesting feature was the relatively mild picric acid poisoning in a burn of a very small extent.

### JAMES MACKENZIE INSTITUTE

#### Gall-bladder Disease

At the James Mackenzie Institute for Clinical Research St Andrews on November 1st Professor David P. D. Wilkie (Edinburgh) read a paper on gall bladder disease and gall stones. After tracing the history or the development of gall bladder surgery he described the types of gall stones at present believed to be of metabolic origin. Single radiate cholesterol stones found as a rule in stout females associated with afebrile attacks of colic but with little disturbance of health and the multiple pigment calculi found most typically in acholic jaundice. In regard to cholecystitis he expressed the view that this disease was almost invariably an intramural streptococcal infection. It was quite the exception to be able to grow organisms from the bile in any but acute cases. The failure of most observers, in this and other countries, to confirm Rosenow's observations was shown to be due to faulty technique and not to any error in the latter observer's conclusions. Dr A. L. Wilkie, working in the Surgical Research Department at Edinburgh had shown that in 85 per cent of cases of chronic cholecystitis a streptococcus could be grown from the cystic gland and this organism on experimental inoculation had shown a selective affinity for the gall bladder. The mode of origin of the multiple cholesterol lithium calcium stones following an attack of acute cholecystitis was described and the origin of the multiple mulberry cholesterol calculi following cholesterolemia with lipoid papillomatosis was illustrated. In discussing the symptomatology of gall tone Dr Professor Wilkie laid stress on obstruction or the narrowing of the gall bladder as the most frequent cause of gall colic on the absence of a muscular coat to the common bile duct, which allowed of the silent residence of a stone in this duct and on the definite muscular contraction of the gall bladder which might be produced by the irritation of the stone. To the duodenal tube there was a certain very limited field of contraction and this was for the bile to leave

uses with infected ducts it gave most useful evidence, in the earlier stages of gall bladder disease when the infection was intermittent it failed to give positive evidence. Of all accessory methods in clinical diagnosis of gall-bladder disease first place was given to cholecystography. The accuracy with which radiolucencies of containing cholecystography with a minimum of examination, were demonstrated. In regard to treatment it was contended that drugs, which merely had a disinfectant action in the lumen of the biliary passages, could not be expected to achieve much. Regarding surgical treatment, the removal of the gall bladder, in the wall of which the infection was located, was advocated for every case in which it could be done without undue risk.

DR CHRISTINA BARNOWMAN (Newcastle-on-Tyne) recently gave a lecture at the Glasgow Eye Infirmary on traumatic and acute and chronic inflammatory conditions of the eye treated with ultra-violet rays. The meeting was organized by Dr John A. Mortimer, and Dr Barnowman was in the chair. Members of the staff of the Eye Infirmary and the Ophthalmic Hospital and others to the number of forty attended. Dr Barnowman claims that her method is unique in that she administers it through the closed eyelids, and remarkable in its success in that scientists hold that there is little penetration of tissue by the ultra-violet rays. The lecture was illustrated by lantern slides of cases, and was followed by much discussion.

## Reviews.

### RECENT ADVANCES IN OPHTHALMOLOGY

The progress of physical science is no better exemplified, so far as medicine is concerned, than in recent advances in ophthalmology. It is true that these advances have been in the main elaborations in the technique of methods of clinical examination rather than in treatment. Ophthalmology has for many years been noted for the exactness of investigation and diagnosis which attends it, and the now recent years have been admirably served and explained under the title *Recent Advances in Ophthalmology*. His aim has been to fill the gap between the standard textbook and a bulky and cumbersome periodic literature, and the success of his effort is not in doubt. There are chapters on light, physiological optics, emulsiology, methods of diagnosis, general physiology, pathology, phototherapy, and neurology. The senior student of ophthalmology, according to his bent, will find the physical side or the pathological and morphological of the greater interest.

Recent correspondence in our columns on the claim of treatment of cataract by ultra-violet rays makes certain passages of special interest. The collected evidence shows that both ends of the spectrum, the ultra-violet and the infra-red, exert a profound effect upon the eye tissues, and that these are not antagonistic, and may be destructive.

Whenever the cornea is exposed to short waved radiation within these limits an *abiotic reaction* occurs after a latent period the length of which varies with the intensity of exposure, but averages six to eight hours. The histological appearances of the fully developed reaction are characteristic. The surface epithelium shows a swelling and irregularity of its cells, the cells are killed and this layer is desquamated. In extreme lesions the cell proteins are coagulated and an opacity is formed. This later becomes highly vascularized and tends to disappear, leaving a soft, transparent scar.

Heat rays on the other hand produce a lesion which is entirely different. The epithelium remains normal, the stroma is uniformly hazy and swollen. In extreme conditions complete destruction of the endothelium and results in permanent protein coagulation occurs and opacities develop which tend to be

Of effects associated with the lens it is said  
'Here part of the light gives rise to fluorescence the region of the greatest effectiveness being in the long ultra violet from

*Recent Advances in Ophthalmology* By W. Stewart Duke Elder  
M.D. D.Sc. F.R.C.S. London J and A Churchill 1927 (Demy 8vo  
pp vi + 343 73 figures, 4 plates 12s 6d)

3,500 to 4,000 Å. When light passes through a fluorescing substance the particles of the substance become light sources themselves, emitting light of a wave length differing from the incident light, preponderatingly longer, but sometimes shorter. The effect of this phenomenon is regarded differently. Considering that its production implied absorption Schanz (1915 22) looked upon it as delicious. On the other hand, from the work of Buige (1915), who correlated a decrease of fluorescence with an increase in the coagulability of the lens proteins, it may be looked upon as a protective mechanism, whereby the active short waves which might induce coagulation, are changed largely into long (visible) waves, by which means their energy being in a more transmissible form, is disposed of more safely.

In the section dealing with morphological and neurological matters we find an admirable summary of recent investigations on the representation of the field of vision in the cerebral cortex, which has been especially associated with the work of Dr Gordon Holmes and Sir W. T. Lister. It gives in a very brief space a highly instructive account of the observations and of their bearings.

Mr Duke Elder is to be congratulated upon the excellent work that has been under investigation for so many years and with changes that are so small that their bearing is apt to be overlooked.

### HEALTH, ANCIENT AND MODERN

The science of public health—or preventive medicine, as it is becoming more fashionable to call it—has within recent years made notable advances in immunology and other fields. Historically considered, it has, as a rule, progressed in a fitful manner, yet a unity of purpose appears to run through it even from ancient days. This essentially unity has been well brought out by Sir Arthur Newsholme, in his work *Evolution of Preventive Medicine*, in which he traces the development of public health from early to recent times. He begins by noting the value of the Greek gymnasium with its wrestling, games, and baths. He refers to the rules of personal and communal health set forth in the Book of Leviticus. He admits that the low standards of church were in part a revulsion from pagan luxury. He speaks of the stimulus given to experimental science by Paeleus and Roger Bacon, and says that Vesalius and William Harvey struck the death-knell of dogma. He commends Sydenham and his services to medicine, though he does not explain why that robust iconoclast and former ironside fled from the plague of London. His notice of Sn George Baker's essay on the Devonshire colic is of much interest, and Baker's impressive concluding words are quoted.

The author perhaps attributes the decline of leprosy in Europe too certainly to the enforcement of segregation. The treatment of lepers in the Middle Ages was often merciless enough, but, side by side with those stern measures, there went on the practice of begging by lepers, which brought them about the habits of men, and another practice, that of begging in lepers' gowns, by poor citizens authorized by city councils to lure the gowns for this purpose. Such freedom could not be strongly conducive to the repression of the disease. It seems quite probable that the prevalence of leprosy was checked simply by the general improvement in standards of living which marked the passing of the Middle Ages. The disappearance of plague from Western Europe at a later date is traced by the author to this kind of improvement, which in this case meant the growth of conditions that "would keep its out of houses." The replacement of the black rat by the brown, while it may have accelerated the decline of plague, could scarcely have been the primary cause, for the disappearance of plague from Western Europe was well advanced before the brown rat came. Heiden, whom the author thinks eulogistic, is not the truth when he says

Our exemption from the plague is not so much to be attributed to any accidental absence of its exciting causes as to our change of manners: our love of cleanliness and ventilation, which have produced among us I do not say an incapability, but a great unaptness any longer to receive it.

In the section on sanitation and social improvement the  
*Evolution of Preventive Medicine* By Sir Arthur Newsholme M.C.B.  
M.D. F.R.C.P. London Baillière Tindall and Co. 1927 (Cr 8vo  
pp vi + 226 6 plates 11s 6d net)

point is effectively made that the rising standards of conduct in recent years with respect to destitution, cruelty, intemperance and vice have been a potent aid to hygienic progress. The housing conditions of early modern England are briefly but vividly described and the degradation of life in the London slums of last century is illustrated from Charles Kingsley. Pitt's window tax is referred to as we look back on it now with wonder. What public health in Britain owes to the Navy and Army is cordially acknowledged, as it should be. The Irish outbreaks of typhus fever are referred to as historically important. Proper Poor Law relief reduced their prevalence by immobilizing ambulatory cases, it here who would otherwise have wandered across the country in search of food or shelter. An account is given of the disappearance of cholera, of Pettenkofer's ground water theory and of vaccination against small pox. The work of Charles White of Manchester on the management of pregnancy receives merited commendation. Scoury is well discussed and also infantile hygiene and the book closes with a review of the modern public health era with its specific immunizations against disease.

Where so much is admirable criticism is reluctant. But Robert Boyle was a relative of the Earl of Cork and the account of the plague of the 1600s or Old Testament story is not in 2 Samuel 13 but in 1 Samuel 1 and 16.

The author alike by his wide information and administrative experience and by his sympathetic appreciation of the work of the pioneers is specially qualified to recount the progress of preventive medicine. It emerges from his narrative that the social and other factors which operated for the control of disease long before the new scientific era dawned may still be promoting good standards of living work in the cause of health. This message should fall on attentive ears. The principle which inspires it must guide the policy of all enlightened administrators.

The author refers in his preface to his two winters' work at Baltimore. Another distinguished Englishman who in 1842 visited the United States for a shorter period came home and wrote his *American Notes*. In dedicating his book to his gracefully does to Dr W H Welch director of the school of hygiene and public health at Johns Hopkins University Baltimore. Sir Arthur Newsholme is the monumental city will recognize his made a better return than Charles Dickens.

### THE HISTORY OF HEART DISEASE

Dr R O Moon, the assistant registrar of the Royal College of Physicians in London who by his works on the 'Relation of medicine to philosophy' (1909) and the FitzPatrick Lectures (1921-22) on 'Hippocrates and his successors in relation to the philosophy of his time' has shown that he is a worthy follower of Linnaeus the scholar physician and founder of the College has now brought out an eminently readable sketch of the *Growth of our Knowledge of Heart Disease*. It begins with Hippocrates and ends with Sir James Mackenzie and Sir Thomas Lewis. As is only meet and right with the approaching celebration next year of the tricentenary of the publication of the *Exercitatio de Motu Cordis et Sanguinis in Animalibus* there is a clear account of Harvey's discovery based on deduction and proved by experiment as laying the foundation stone of physiology though many years elapsed before any important addition was made to the knowledge of cardiac disease. In fact up to the time of Raymond Vieussens (1695) who wrote much on the morbid anatomy of cardiac disease and paid minute attention to the clinical picture the notion that the heart could not be diseased still persisted.

Science may be regarded as the first physician to write a treatise solely devoted to cardiac disease in the middle of the eighteenth century. The history of digitalis and digitalis preparations both so closely associated with English names is outlined and the influence of the study of physical signs due to Auenbrugger, Lennie, and Corvisart, is shown. The list named who was the advocate and popularizer of percussion and the teacher of Laennec used the word 'anemism' to mean dilatation of the heart.

but insisted on the frequency of cardiac disease which he regarded as second in frequency only to tuberculosis. Dr Moon points out that, while in the later part of the last century the detection of organic cardiac disease was much elaborated, the functional efficiency of the heart is now demanding similar attention and elucidation.

### TREATMENT OF THE FEEBLE-MINDED

Our tenth volume of the Harvard Studies in Education is entitled *What shall the Public School do for the Feeble-minded?* It is, of course, an American book, and therefore the 'public schools' referred to in the title are what would be called in this country the public elementary schools conducted by the local education authorities. In this volume Dr GRAY PRATT DAVIS professor of education in the State Teachers College, Indiana, Pennsylvania makes a valuable contribution to the subject or the special training and classification of mentally defective children. It is based upon the work of Dr W E Fernald of the Massachusetts School for the Feeble-minded at Waverley. It is truly said that the death of Dr Fernald in 1920 'robbed the medical and the educational world of one of its greatest benefactors'. For just as Binet worked out a systematic plan for testing the degree of intelligence, so Fernald worked out a systematic plan of scientific procedure for the training of those whose intelligence is found to be below the normal.

Dr Davis has had two advantages of close association with Dr Fernald and his successor, Dr Ransom A Greene and his book consists mainly in the detailed exposition of a practical and scientific course of instruction to be followed with the various grades of feeble-minded children. It is thus of prime interest to teachers engaged in such instruction but it should appeal also to the medical profession as well as to many others who are interested in the social problems associated with mental deficiency. In accordance with modern conclusions mental deficiency is not regarded as a matter of intelligence merely emotional and other defects and instabilities are essential factors in the problem. Nor is it now held that every feeble-minded person is a social danger who ought therefore to be subject to permanent institutional control and segregation. A relatively large proportion of those who are defective in intelligence are socially well behaved if they have had suitable training and have even a light amount of supervision. Nor is it by any means impossible given such training and supervision to make feeble-minded persons economically self-supporting or even profit earning though this must always be in the lower ranks of industry and in tasks of a simple and routine character.

A very valuable chapter on 'The results of the salvaging process' gives the best sets of statistics on the matters that we have seen. The figures and conclusions of this chapter deserve the most careful attention and consideration. The tables and charts throughout the book are, indeed, all illuminating. As a compendium of present knowledge of the problem of feeble-mindedness especially in its pedagogical and social aspects, Dr Davis's book is a most important piece of work.

### HEALTHY GROWTH

SIR ARTHUR KEITH in his preface to *Healthy Growth* by Dr ALFRED MEADON medical officer to the Manchester Grammar School says that the author, by advancing the height weight chest girth and vital capacity has constructed standard ladders each rung representing the stage which the average boy reached with each additional year. Having obtained such ladders it was easy to say how many rungs any particular boy was ahead of or was short of the average boy in particular directions the average boy became the benchmark for all the other members of his year.

There is much the author has to be added to the use of almost any height-weight index as a standard of nutrition for

What shall the Public School do for the Feeble-minded? B-Gu Pratt Davis Harvard Studies in Education Vol. X (Cambridge) Ma Harvard University Press London Milford Oxford University Press 1927 Demy 8vo pp xxiv + 252 1s. 6d.  
Healthy Growth by Alfred Meadon M.D. With foreword by Sir Arthur Keith M.D. Dse F.R.C.S. F.R.S. Oxford Medical Publications London Milford Oxford University Press 1927 (Demy 8vo) pp xxiii + 343 3s. 6d. (3s. 6d.)

very early childhood, and of the ponderal index as a standard of nutrition for very early adolescence, but when we are considering the physique of adolescent schoolboys we ought to study the dynamic as well as the static factors of healthy life, and indices which test robustness and stamina must include the factor of chest girth."

Dr. Mumford claims that excess or defect in all forms of activity—whether the emotional activity that underlies high moral character, the mental activity that underlies high intellectual attainment, or the physical activity of sports and games—is associated with specialized forms of respiratory activity. "No attempts to inculcate or remedy defects, or to provide the fullest scope for the proper development and display of excess, will prove fundamentally successful which are not based upon a very thorough knowledge of the respiratory powers."

A research was carried out on the buoyancy of boys in the swimming bath, and then what is termed "the crude buoyancy index" was founded on height, weight, and chest girth, and used for comparing different boys, or groups of boys, one with another. 2,500 cases were tested to establish a mean normal. The athletes were well above the normal, particularly in chest girth and vital capacity. "It was interesting to note that those who obtained high places in long distance swimming rarely obtained high places in running." The test introduced for flying officers by Flack, of sustaining a column of mercury 40 mm high by the breath, can only, in Dr. Mumford's opinion, be regarded as a test of nerve stability—of the sustained co-ordination of the circulatory and respiratory mechanisms during prolonged effort. A fortnight's holiday raised the average five seconds in each of three classes of thirty boys. Dr. Mumford is now investigating what he terms the respiratory index—the relation of unit of exchangeable air to unit of body volume. There is, he says, "sufficient evidence of a positive correlation between physical growth and intellectual progress for making very ample provision for all the circumstances favourable to body development, especially for more fresh in physical exercises, recreation, and adequate rest."

While the group of boys who entered for the school leaving certificate examination taken as a whole showed an acceleration in bodily growth above the normal at all ages in all categories, absorption in study for this examination retarded the development of the chest.

"To boys, as well as to masters, these often colossal organized mass examinations are a hindrance to individuality and readily become a nightmare to overwrought boys. The judgement which selects for commendation the few boys at the top and virtually ignores the others is not only incomplete, but an untimely summary of the work of the school."

Dr. Mumford is of opinion that of all the different bodily impulses which affect the unconscious mind—raising or depressing the feeling of confidence and well-being—the most important "are those related to muscular tone and balance and external pressure."

"Given good stamina a boy will profit by his educational opportunities and will gradually dominate his circumstances. Given poor stamina circumstances will too often dominate him. It is then of even more importance to possess standards of stamina than standards of growth, especially when we are dealing with children in attendance at public secondary day schools where any limitations of bodily activity will exert a particularly injurious influence. The commonest form in which lack of stamina reveals itself in the very young child is the tendency to disturbances of temperature balance—states of feverishness such as are associated with colds and sore throats—or with such disturbances of food transformation as lead to recurrent headaches, bilious attacks, etc."

Dr. Mumford describes three types of boys. The boy who is capable of putting forth marked muscular strength appears to be broad throughout, not necessarily tall, coarse muscled, slow in starting, powerful in execution. The well developed agile boy who is capable of rapid movement, is broad in shoulder with wrist clearly marked. The third type of boy is capable of marked output of energy, but is not usually associated with high physical power and fitness, since he rarely excels in games. Yet after adolescence this type is associated with great persistence. Such a boy is usually tall and spare with muscles of the arms often specialized for some handicraft. His vital capacity generally is high. He is often childish in some directions as advanced in others. He loses heart easily and needs much food, is easily exhausted and requires plenty

of sleep, he totters for a longer time the infantile susceptibility to bacterial invasions, and in his case greater care is necessary to avoid tuberculosis and rheumatic fever than is required for his more robust fellows.

An inquiry into the types of skin of the boys led to the following classification:

*The chilblain type*, with hands cold and of blue tint mentally slow, will not make an athlete, and stands exposure to cold badly, best treated by graduated exercises and tanning the skin to respond to temperature changes.

*The pink skinned warm blooded type*, of spare build and quick heart. Physical and mental activity marked, sexual development slow, easily overruled, but capable of a great temporary output of energy.

*The oily skinned type* has thick skin, and the hair may be in excess and curly or coarse. He is short in trunk, broad chested, and often fat. His sexual development is early. He has great mental and physical striving power, resists exposure well, is muscular rather than agile, and is slow in response.

One of the author's conclusions is that under the conditions of a modern day school damage rarely, if ever, occurs to a completely healthy heart as the result of overtraining and exercise. It generally follows incomplete recovery from some minor febrile condition.

"It is painful to see the number of boys who, having at one time been debilitated from all physical activity on account of real or sometimes even of imagined heart weakness continue to be held back from all games, and the proper exercise, which is the real means of anchorage or cure."

In stature, weight, and circumference of chest the present-day average boy of 15 compares favourably with his predecessor of forty years ago.

Of great interest is the account given of an open air school. At the Greengate open-air school at Salford an attempt is made to stir up the normal process of physical and mental growth of the "inert toddler of pre-school age suffering from under-development and malformation due to rickets, often complicated by serious tubercularization." The young child kept in bed may gain in height and to some extent fatten, but the muscles, heart, and respiratory organs need development by exposure to cooling air and exercise, while the rickets require to be met by the action of unfiltered sunlight. At Greengate the children live and sleep in the open air, or in a shed entirely open to the south and with louvers open to the north. There is no artificial heating other than that required to dry clothes and blankets. Warmly clad and well fed, the children do splendidly, and soon come to discard extra clothing.

"Then breathing became deeper the blood in their skins became richer, and consequently their complexions improved, the catarrhs of the nose and throat, and the febrile attacks lessened and disappeared. Then nerve energy increased and their muscles gained so much in tone and in co-ordination that their distorted bones of arms and legs, now receiving their appropriate strain, were reformed and took on their proper shape."

A teacher was appointed trained in the new educational methods of spontaneous choice, but three restrictions were imposed: the children must not interfere with others, waste time, or destroy. Self-control gradually took the place of control by others. They learned to work as members of a keen happy order family. They were able to pay closer attention and to concentrate for longer periods owing to lessening of fatigue. The open air school must come to be the one for all, and be used as a preventive of illness rather than as a cure.

It is a good thing that the masters of the Manchester Grammar School have been wise enough to buck up the services of so excellent a school medical officer and the evidence he has collected will be widely appreciated.

## NOTES ON BOOKS

A HANDBOOK\* compiled in the German language by Dr. H. GRAFSPACH might from its title be supposed to be a dictionary of medical terms but it is more than that. The first section (815 pages) might almost be described as a brief explanatory synopsis of terms used in medicine and pathology and for various diseases. The names and dates of the authors prominently identified with advances in knowledge of the several diseases, and a note of what they did, are included. This section is well up to date and includes much chemical and biochemical information bearing on medical problems. The second section (313 pages) gives brief biographical notes and

*Medizinische Worte und Vorschlägebuch* von H. Grafspach. 1927. (44 x 64 pp. xvi + 1128. M 70) (See also Alfred Topfmann 1927 (44 x 64 pp. xvi + 1128. M 70))

dates of all the authors who are referred to in the first. It makes no pretence to be a complete list of all the names well known in medicine past and present but brief biographies are given of many of the great men of science who are dead. In the case of living authors, their names, addresses, present appointments and work for which they are best known are referred to. The bulk of the names are frankly those of well known German authors, but there is a sprinkling of British, American, and French names. This last part of the book is, however, far from representative and many well known names are missing. The first section of the book is excellently done and filled with useful information. The second part might be valuable to English speaking people in providing the full names and present postal addresses of the bulk of living German workers on medical problems.

In his *Fundamentals of Dermatology* Dr ALFRED SCHULEK, professor of dermatology and syphilology at the University of Nebraska School of Medicine has provided students and general practitioners with a clear and concise account of diseases of the skin. The work consists of two main parts. In the first, which is introductory, an account is given of the anatomy and physiology of the skin and this is followed by a description of the general symptomatology, diagnosis and treatment of diseases of the skin to which some dermatological maxims and a classification are appended. The second part, which forms the bulk of the book, contains in alphabetical order a brief exposition of the etiology, pathology, symptoms, diagnosis, prognosis and treatment of each disease. The text is freely interspersed with illustrations, most of which are original.

The second edition of Dr HENRY C. SCHOLEK's work on *Diphtheria, Measles, Scarlatina*, of which the first was published in 1920 and reviewed in our issue for April 24th of this year has been rewritten and enlarged. The book now contains an account of the Schick and Dick tests of the Schultze-Charlton reaction of active immunization against diphtheria by toxin antitoxin or inactivated, and the prophylaxis of measles by convalescent serum. The work is of value as representing the experience of one who has had a very wide acquaintance with these diseases, but is by no means exhaustive as it contains no historical or epidemiological notes. Few references are made to the work of other writers and there is no bibliography.

The cowkeeper and dairyman will find much up-to-date information in *The Production and Distribution of Clean Milk*, by Mr A. T. R. MATTHEW. The reader is first told that clean milk cannot be produced without light water and steam and is then led through the whole process from the sanitation of cowbeds and the clipping and cleaning of cows to the distribution of milk in bottles. The systems of bonuses to producers and workers based on the bacterial content of the milk are explained and tables are given to show the extraordinary improvement obtained by individual farmers. The increasing use of milking machines is noticed but the producer is warned that any saving in the labour of milking is counterbalanced by the time necessary for cleaning and sterilizing the plant. Mr Matthew is convinced that with well organized routine it need not take much longer to produce clean milk than dirty milk. Unfortunately the power to organize is not universal and the shortage of agricultural labour increases the difficulties of the producer. However the bonus system of the milk distributing firms is no doubt helping to improve matters and their pasteurization of the commodity keeps contamination within reasonable limits.

## PREPARATIONS AND APPLIANCES

### AN ELECTRICALLY WARMED BLANKET

We have recently had an opportunity of examining what is known as a Thermega blanket and of testing its action. It is designed to supply hot water bottles and warming pins and certain electric heated warmers which are not without their drawbacks or actual dangers. Thermega is a blanket the standard size of which is 44 by 32 inches. The material is washed and when the folds are placed a flexible conductor which traverses the space between the surfaces many times, before it ends in the attachment where it entered the blanket. It is arranged in parallel lines between 2½ and 3 inches apart and the length of warmed wire in each blanket is very considerable. The temperature reached is only about 104° F. so

that all danger of burns is obviated and as the conductor is already, as it were, short-circuited there is no risk from any damage to the conductor which is practically unbreakable. These blankets should be of use for prolonged operations, and in all conditions where it is desirable to use artificial heat in the sick bed. For domestic use as a bed warmer it is only necessary to turn on the current for one hour before going to bed. The cost of current used per hour at 6d a unit is said to be only one farthing.

The Thermega patent of patents for the British Empire are held by Thermega Limited, an organization which we understand to be financed and controlled by the Ex-Services Welfare Society of which Sir Frederick Milner is president. The experiment which is thus being carried out is interesting for it embodies probably for the first time an attempt to find regular work and wages for ex-service men on a strictly economic basis. It was recognized according to Mr Kniv who has directed the social industrial side of the business that these men could not compete in the open market but that they might be profitably employed under the protection of a patent. Apart from the psychotherapeutic side of the undertaking its primary object is to pay a living wage to the disabled workers employed, and to produce a balance sheet showing a profit which must by statute be utilized for the much needed extension of the scheme.

For the last four and a half months twenty-four men have been employed in this work at the Frederick Milner Industrial Colony at Leatherhead. Among them are cases of anxiety neurosis, hysteria and minor degrees of dementia praecox, and Dr Mappother of the Maudsley Hospital has recently reported very favourably on the effects of their occupation in his work. We understand that the Society hopes to acquire other patents, and to extend the scope of its industrial activities in similar directions to this.

Thermega blanket can be obtained at most large stores and surgical appliance firms or direct from Thermega Limited, 94 Pettit France Westminster SW 1.

### CORSET BELTS

Visceropeliosis is the cause of so much discomfort and ill health in a considerable proportion of cases that any effective measure for giving relief is welcome. The mechanical problem of affording support to the dropped viscera is not as easy as it might appear on theoretical grounds, and an ill-fitting or wrongly applied belt or corset may aggravate rather than diminish the subjective effects of this condition. On the other hand the comfort afforded by properly applied support is in some instances almost dramatic and the resulting improvement in general health is frequently very striking.

Madame Rose of 80 Mortimer Street W.1 has for many years devoted special attention to this problem and we have good reason to believe that she has given help and comfort to a considerable number of sufferers. We have received assurances from medical men who have sent patients to her that she gives personal attention to each patient that she takes great care in adapting and adjusting the support to the particular needs of the case and that she shows herself desirous of complying with the recommendations of the practitioner in charge of the patient.

### PEPTIZYME

Peptizyme is a product of Messrs Reed and Carnrick recommended for the purpose of disguising distasteful drugs and also for the relief of disorders of the digestive system. It contains 15 per cent of alcohol and has a pleasant taste that suggests the presence of some volatile oil. It also contains a mixture of the digestive enzymes. The preparation has a pleasant carminative action and appears well adapted for covering drugs which have a nasty taste.

### A PORTABLE BOOK REST

Readeasy is a light and simple form of book rest made with an adjustable trap to sit over the shoulders so that when in use it resembles the tray carried by the itinerant vendor of matches and toys. It is intended to enable invalids to read or write without the exertion of supporting the books in the hands but it is equally serviceable for those who are well. The apparatus can be folded up so that it does not take up much room. It could probably be improved by clips for keeping the pages of the book open rather than leaving the hands free to relieve any slight discomfort caused by pressure of the instrument on the abdomen when a heavy book is being read. The invention of Mr H. H. Arnold of 61 St. George's Road London SW 1.

### PEP PENICIL AND THERMOMETER

We have received from Messrs L. G. Sloan (Pen Corner Kingsway W.C.2) a sample of what they call a 'penicil' produced by Messrs Waterman consisting of a fountain pen, a penicil and a thermometer which they suggest would be a suitable Christmas present or a doctor. The three implements are finished in white lacquer and enclosed in a white case, a white potery and to hold all three can also be supplied. We agree that the set is more suitable for a personal present than for hospital use and a very handsome present it would be. The set can be obtained from dealers in such things the price is 70/- or with the pen and 72/- 6d.

## THE TOXAEMIAS OF PREGNANCY

NOTWITHSTANDING the enormous amount of research and investigation which has been undertaken on eclampsia and the other toxæmias of pregnancy, uniformity of opinion regarding the essential nature of these conditions is still lacking, and so many theories and speculations have been brought forward that eclampsia has been dubbed somewhat derisively "the disease of theories." Much further study and research are needed before this truant can become obsolete and the etiology of these conditions established on a firm basis. Such research should be based both on a clinical and on a biochemical basis, with the careful correlation of the results obtained in both fields.

The report of Cruickshank, Hewitt, and Couper to the Medical Research Council proceeds on these lines, for it is a clinical and biochemical study of 200 cases of toxæmia of pregnancy and of a series of 42 normal gravidæ. The work emanates from the research department of the Glasgow Royal Maternity and Women's Hospital, and the incidence of the toxæmias of pregnancy in Glasgow is shown by an analysis of the figures for the decade 1913 to 1922. The annual percentage of cases of eclampsia among the 23,630 patients admitted during the decade varied from 6.1 to 2.8 of all admissions, this is a higher incidence than is shown by the series of cases collected by Whitridge Williams in America.

Eclampsia is well recognized as a source of maternal deaths, and in Glasgow it was found that the death rate varied from 15.6 to 31.6 per cent, with an average of 22.4 per cent, though it is apt to be overlooked as a factor in the loss of foetal and neo-natal life, the death rate among the infants of eclamptic mothers was more than three times the general infantile death rate in the hospital. Moreover, in comparison with the figures for unselected cases admitted to the hospital, stillbirth was found to be about three times as frequent in eclamptic cases as in general admissions, while premature birth was also distinctly more common than in an unselected series of control cases. Again, among the infants born alive of eclamptic mothers the death rate was also more than three times the general infantile death rate. Taken together, these figures emphasize in a remarkable way the importance of eclampsia as a cause of loss of foetal and infantile life.

This investigation was approached primarily from the clinical side, and a clinical classification of the cases into four groups was adopted. In the first group the patients had albuminuria of renal origin during the second half of pregnancy, most of them having no other signs of toxæmia. Patients of the second group had symptoms of toxæmia in addition to albuminuria, but had no convulsions, the condition being commonly known as pre-eclamptic toxæmia. The third group comprised the cases of nephritic toxæmia, having albuminuria as the main symptom,

accompanied in some cases by cardiac involvement. Although this group is not so homogeneous as the others, the authors consider that its retention is justified, seeing that it includes a well recognized variety of toxæmia of pregnancy. Group four comprised cases of eclampsia with definite convulsions of the usual eclamptic type, together with other signs of severe toxæmia.

The results of blood analysis showed such great individual variations that it was often impossible to diagnose the type of toxæmia from these findings alone, and the analysis of the urine had only a limited value on account of the difficulty of obtaining the complete daily output. Nevertheless the general conclusions which the authors have drawn from their observations seem to be that the peculiarities of the blood and urine which characterize the later months of pregnancy are maintained, and may be exaggerated, in all the forms of the toxæmias of the later months of pregnancy, that though there is no definite azotæmia in ordinary cases in any of the varieties studied, moderate nitrogen retention is not uncommon in fully developed eclampsia, and that the hydraemic state of the blood which is characteristic of late pregnancy and the oedema which develops in certain toxæmic cases do not show any demonstrable relation to the chloride content of the blood or to the output of chlorides in the urine.

Tests of the hepatic function have roused much attention of late, and those here investigated include van den Bergh's reaction, Fouchet's test for bilirubin, Ehrlich's aldehyde test and Schlesinger's test for excess of urobilin and urobilinogen, Gmelin's test and the iodine test for excess of bilirubin, Oliver's and Hay's tests for excess of bile salts in the urine, the laevulose tolerance test, the nitrogen partition in the blood and urine, the coagulation time of the blood, the fibrinogen content of the blood, lipase in the blood, Widal's hæmolytic crisis, and glycerone acid synthesis. The authors' results indicate that none of these tests is of real service in the diagnosis or prognosis of the various forms of toxæmia of pregnancy. Normal gravidæ with no clinical evidence of hepatic insufficiency gave a certain proportion of positive results, and in the abnormal cases no correspondence was found between the results of the liver tests and the severity of the clinical manifestations. These results are at variance with those of other recent workers. Thus Berkeley, Dodds, and Walker obtained positive results with some of these tests only in eclamptic patients or in cases so critically ill as to require the induction of premature labour, they suggested that the results of these tests might be taken as a reliable indication as to the necessity of terminating pregnancy in cases of albuminuria. For this suggestion Cruickshank, Hewitt, and Couper can find no justification, and their general conclusion from the study of these hepatic tests is that there exists as yet no sufficiently sensitive and reliable method of examining hepatic function.

Turning to the results of the present investigation in relation to current views on the etiology of the toxæmias, it is pointed out that before entering upon such a discussion it must be kept in mind that true eclampsia does not occur spontaneously in animals, that it has not been produced in its entirety experimentally in animals, although certain features can be produced by the experimental injection of various substances, including more particularly placental tissue extracts. Eclampsia and the allied forms of toxæmia are essentially associated with pregnancy, and do not

can put them it, and an experimental conclusion can be regarded as identical with them unless it is produced in pregnant animals and does not appear when non-pregnant animals are similarly treated.

The authors have found no clinical, bacteriological, histological or experimental evidence that the condition is due to any animal or vegetable parasite or to disturbance of endocrine glands; they think that the cause is to be found in some substances elaborated in the foetal or placental tissues or produced by some disturbance in maternal metabolism resulting from the pregnant state. After these various factors have been thoroughly discussed the conclusion is reached that if the toxemias of pregnancy have a common cause it is some form of auto-intoxication by the breakdown products of placental tissue, probably some of the higher products of protein metabolism which like the breakdown products of leucine have a powerful action even when present in small amount. Although they do not mention histamine among these products it would appear to fulfil these requirements and it has recently been credited especially among American workers with being a possible etiological factor in the causation of eczema.

A critical consideration of this report along with other recent work on this subject shows that we are still far from having reached any really satisfactory explanation of the causation of eczema and the remaining toxemias of pregnancy and many and intensive researches will still be needed before such a result can be reached.

## LEONARDO BIANCHI PSYCHIATRIST AND STATESMAN

Neurology and psychiatry suffered a great loss by the sudden death last April of Senator Leonardo Bianchi. Emeritus Professor of Nervous and Mental Diseases in the Royal University of Naples, at the age of 80. In a newell address when relinquishing his chair he said that discipline, obedience and devotion to the welfare of the community should guide the lives of men. "Duci!" Erect in stature and let it be your law. In these words Bianchi epitomized his own career. He became assistant physician to the Neapolitan Provincial Asylum in 1882 and director of Palermo Asylum in 1887. His teaching career began in the following year when he was made professor of extraordinary of psychiatry in the University of Palermo. His neurological research work and already considerable contributions to clinical psychiatry led to his return to Naples, where in 1890 he was appointed professor of the psychiatric clinic and superintendent of the provincial asylum and professor of nervous and mental diseases in the Royal University. He established histological, bacteriological and physiological laboratories and before long became the great master of Italian neuro-pathology and psychiatry in eminence he remained until his death.

For over a quarter of a century, Bianchi's genius and commanding personality thus dominated Italian psychiatry. He was an exceptionally good teacher, a clear writer, a brilliant public speaker and a fascinating conversationalist. His wide sympathies, broad outlook and close study of the many social problems affecting the welfare of his country, together with his high sense of public duty, brought him into politics where he reached the highest positions. From a deputy he rose in 1905 to Secretary of State for Public Instruction and finally was elevated to the Italian Senate. It must have been a unique occur-

rence for a man to be university professor, an asylum superintendent and a Minister of State all at the same time. Bianchi's resignation of his chair at the University in 1923 did not mean a lessening of his activities; on the contrary, he was now able to interest himself more deeply than ever in the problems of eugenics and mental hygiene and to complete the revision of his famous textbook of psychiatry, the third edition of which appeared in 1924. He also took a keen interest in the legal and administrative aspects of psychiatry and in 1922 reported to the Italian Legislature on the crying need for reform of the Italian law relating to asylums and the insane. He deplored as we do in England the fact that the lunacy laws of his country were inspired by a desire more for the public safety than for early treatment of the mentally afflicted and the administration of asylums on hospital lines. He drove his point home in a great oration before the Senate in 1922 in which he said that the shortcomings of Italian legislation had greatly tended to increase insanity rather than diminish it. He urged the free admission on purely medical grounds and not as a result of legal investigations of early and acute cases into psychiatric clinics and special departments of the asylums and a revision of the cumbersome method of discharge of patients which remained far too long in the mental institutions convalescent patients and others fit to be at home.

Bianchi's researches into the anatomy and physiology of the nervous system, his work on aphasia and his discovery of the presence of bacteria in the blood of some cases of acute delirium were well known in this country but the appearance in 1906 of the English edition of his textbook on psychiatry was a refreshing experience to English psychiatrists then rapidly becoming Germanized. Nothing so comprehensive had ever been available in our language. The great advances made in this subject in recent years by the anatomist, histologist, pathologist, bacteriologist, neurologist, psychologist, sociologist and clinical psychiatrist were all built up into a great biological edifice on the solid foundation of research and clinical experience. No one person has contributed more to this synthesis than Bianchi himself. It was in 1868 that he began his famous experimental researches and clinical observations in regard to the physiology of the frontal lobes which satisfied him that these were associated with the highest and latest evolved psychic functions, especially the social sentiments. His completed teachings in this relation were published in 1922 in a volume entitled "The mechanism of the brain and the functions of the frontal lobes."

Bianchi's conceptions of life and the relationship of mind and matter are naturalistic throughout. He avoids metaphysical or *a priori* entanglements and is content to assume the transformation of cosmic into neural energy and its psychic equivalent. What is found in the development of the somatic organism is present also and without substantial difference in the evolution of the psychic organism or mind. Life from the monad to man is a dynamism and intelligence its subjective side. Thus intelligence is the consciousness of life and is manifested through the wonderful mechanism of the nervous system. Psychic life commences with very simple and uncertain manifestations and step by step through progressive assimilation of the forces of Nature it rises to the most potent realization of Nature itself in the forms of thought and consciousness. Like Maudsley and Huxley he is a worshipper of Nature. He speaks of the infinite

resources of a beautiful and generous Nature which endowed matter with life and mind. The cosmic forces of Nature continue to dominate its highest product, man. The mind is absolutely dependent upon matter, and only reached through matter. Man is therefore merely an instrument of the cosmic forces from which he has evolved. The nervous system changes the cosmic energies into psychic equivalents. The psychic function is engrafted upon the great trunk of organic function and is affected by all its modifications in health and disease. Binet thus teaches materialistic monism pure and simple. Neither psycho-neural or psycho-physical parallelism nor interaction has a place in his psychological conceptions. He excludes psychogenic factors in his etiology of mental disorders, except as predisposing to the real causes, which are physiogenic. In the third edition of his textbook he condemns the Freudian doctrines, especially that in regard to the part played by the infantile libido. He regards psycho-analytical methods of treatment as dangerous. Nevertheless, the unconscious mind of Binet's psychology is the largest psychic field—it is the great storehouse and laboratory of the mind, and capable also of instantaneous synthesis and new reactions. In this respect, and in many others, his thought is Mandley thought.

His contributions to physiological psychology and psychopathology are a greater memorial to Binet's genius and work than his clinical psychiatry, though his clinical descriptions are unrivalled. He never attained to so high a position in the world of psychiatry as Kraepelin did, but his net was more widely cast and the catch of greater variety. Like Kraepelin, Binet was remarkable for his inspired devotion to scientific ideals in his lifelong endeavour to solve the many problems which psychiatry presents, and he is worthy of a lasting place in our memory.

### LATE RECURRENCES OF CANCER

THOUGH it is obvious that recurrence of a cancer after an operation planned to eradicate it must be due to an incomplete removal of the malignant cells, either because a nest of them is left untouched or because during manipulations some few are dispersed amongst the normal tissues, it is difficult to account for the extraordinary length of time that sometimes elapses before these isolated cells exhibit their inherent proliferative powers. It is generally recognized, in judging the effectiveness of an operation for cancer of the breast for example, that a period of three years is totally inadequate, even a five year period is not to be relied on. It is true that, if an individual who has been operated upon survives so long without recurrence, the surgical procedure adopted must be regarded as successful, especially in view of the fact that useful years are added to a life at a time when expectations of living to old age are relatively low, and it may also be true that in an individual who has survived the five year period the chances of a recurrence manifesting itself grow steadily more remote, but that there may exist a contingency towards recurrences, apparently for the rest of the individual's existence, is not generally appreciated.

The report presented by a committee of the Medical Society of London—published in abstract at page 1082—based on replies by surgeons to a questionnaire regarding the subsequent history of patients who had survived a ten year period is exceedingly valuable, and to some it may be surprising. At one and the same time it demonstrates that freedom from recurrence is

the rule after that length of time, while it shows that in quite an appreciable percentage very late recurrences are possible. Hitherto such very late recurrences have been regarded both by clinicians and by pathologists as somewhat rare curiosities, but the report provides us now with information in a more exact form. No one will deny that even the most admirably planned radical operation, according to our present knowledge, depends for its success on a certain amount of luck, with the obvious corollary that the more scientific the operation the more is chance eliminated. From a primary tumour the modes and paths of spread of malignant cells are by no means uniform or entirely known. The lymphatic vessels which may carry the cells are legion, and their distribution is only ascertained as regards the main channels, and then only by composite pictures, the cells may spread in them by isolated and discontinuous emboli with the direction of the lymph flow, or by continuous processes against the stream, and it may be that the stream is not always in the same direction, the cells may reach different sets of lymphatic glands in different cases, and the relays are so numerous that groups are not always invaded in their direct order, some cells may go by way of axillary glands, some through intercostal channels, some down nodes along the superficial tissue, some to the other breast, and so on. No one can foretell the particular liability in an individual case, at the best the operator can only form what experience has shown to be an average picture. Further, the cells may be conveyed by way of the blood stream, and then subsequent course cannot be forecast. The chances, then, of some cancer cells escaping the control of the surgeon are very considerable.

In view of the great diversity of paths of dissemination, and the knowledge that isolated groups of cancer cells may lie quiescent for many years without exhibiting their characteristic properties, it may be asked whether at any time a surgical excision of a cancerous breast really succeeds in removing from the economy all the malignant cells. The processes at work that keep the activity of the cell groups under rigid control for so long are only manifest when that control fails. In how many cases is that control maintained? This may be, and probably is, a question without practical value for the moment, but, nevertheless, the definite observation of so many very late recurrences points to the fact that the body has its own defensive mechanisms against malignant cells, and the elucidation of such mechanisms is of absorbing interest to research. Much investigation has been done, but little accurate information has been forthcoming, and, as always when observation has been fruitless, speculations and statements of personal belief hold the field. No purpose is to be served by recounting them. The Medical Society's report fails to correlate the freedom from or liteness of, recurrence with any observed characteristic. The histological characters of the primary growth do not throw any light on the matter, nor do the microscopic appearances of the late recurrences often reveal any plausible reason for their tardy outbreak. Sometimes, indeed, a small and slow recurrent nodule may show a relatively immense amount of dense fibrous tissue imprisoning a few lines of cancer cells, and it is tempting to regard this fibrous tissue as a bulwark set up by the body against the cell proliferation. The undoubtedly good effects of radium or x-rays on certain malignant tumours seem to be due in the main to the stimulation of fibrous tissue with its indirect action rather than to selective lethal action on the cancer cells. It is the custom of

some surgeons to subject their cases after breast excision to rithidions, in the hope that any few cancer cells left behind may be destroyed thereby. It the rays have no selective action on malignant epithelium the proceeding would seem to be of little value but it is hoped that the fibrous tissue may be stimulated to defensive action, then it may not be wholly illusory though controlled observations on the effects do not tend to confirm the utility of the method. The explanation of the phenomena of late recurrences is bound up with the mysteries of the inherent proliferative properties of tissue cells properties that all cells possess. Until we know more about the growth property of cells how proliferation can be stimulated and how it can be checked, no explanation can be satisfying.

### HEALTH OF THE SCHOOL CHILD

THE Chief Medical Officer of the Board of Education, in his annual report, the review of which is begun in this issue, claims and we think truly, that year by year the school medical service and all that it stands for is winning a larger degree of the public confidence. It is of interest to note what a fruitful vine has sprung from the sowing of some few energetic and inquiring doctors of a previous generation. Sir George Newman claims that his report serves the interests of the local authorities and, to might add, of medical practitioners also. Members of local authorities cannot always get a view of the whole as distinct from their own part for often they cannot see the wood for the trees. The report invites them "to behold the extensive vista which lies before them, and to enter the promised land, one where the children of a great race may become their best, a land of perpetual youth." Their aim should be "to prepare the child for education and for citizenship." What a great war they have to play in the life of the nation is realized by few. It can be brought home best by the recognition that of all the children in the country between the ages of 7 and 14 years, no less than 80 per cent are turned in the elementary schools. Between the ages of 9 and 10 the total is as high as 95.3 per cent. In this year's report stress is laid upon the importance of the earliest years of the child's life and particularly upon what are called "pre-school" years. This is the time when the ground is being prepared and the susceptible soil of the child's body, within the limits set by heredity made wholesome or unwholesome a suitable nidus for the beneficial agents of health and life or for the destructive agents of deterioration and death. When the school medical officers are called upon to begin their oversight of the school child—the entrant of 5 years of age—it is found that "one quarter to one-third need medical attention." As the quotation from the report of the school medical officer for London puts it, "The school medical service is a receiver of damaged goods and spends most of its time and energies in patching them up. But there are hopeful signs that the school medical work done for and upon a previous generation is bearing fruit and that there is less ignorance and carelessness amongst the parents. There is certain evidence that the children are to-day stronger taller and heavier than the children of 1907. And since we have been told on high authority that feeding was more horse races than tanning, the correlation of the two is obvious."

### THE LEAGUE OF NATIONS AND DANGEROUS DRUGS

In an annotation in the JOURNAL of October 22nd (p. 746) reference was made to an extraordinary session of the Advisory Committee of the League of Nations on the Traffic in Opium and other Dangerous Drugs. This session was held to consider the situation in regard to illicit traffic,

the proposed 'international syndicate of drug manufacturers,' and other cognate questions. The report of the committee is now before the Council of the League. It is a somewhat verbose document. It deplores the slow progress with the ratification of the Geneva Convention, and laments that only three of the nations now represented on the Council of the League have yet ratified, while the effectuation of the treaty requires four more ratifications by such States. It had before it reports of eighty-three seizures of illicit traffic "amounting in the aggregate to tons of morphine and direct morphine in all parts of the world," a disclosure which the American delegate called "infinitely serious." It was stated that there were six, forty factories in the world controlled by eight nations and that if the drug were effectively controlled and each country discharged its international obligations "the drug problem would be solved." The committee accordingly urges upon the Council or the League the adoption of the principle "that all factories manufacturing dangerous drugs should be owned or adequately controlled by their Governments." This raises a political question or of the first magnitude, it recalls the contentions which have arisen in connexion with proposals to nationalize the liquor traffic and it opens the problem of the identification of the State with a trade admittedly dangerous. The committee appears to have been engrossed with questions relative to the traffic in manufactured drugs, while the more fundamental considerations of the control of the production of opium and the coca plant seem to have been thereby obscured. Signor Cavazzoni, the Italian delegate who at a previous meeting of the committee had unsuccessfully urged a rationing of the production of dangerous drugs in accordance with what were held to be the principles of the Hague Convention, again urged that the disappointing results were due to the fact that the methods adopted were wrong. He submitted a detailed scheme which he held would "enable all Governments to apply with uniformity and certainty the principles underlying the Conventions of the Hague and Geneva." The scheme however appears to have been side-tracked, and, along with the German delegate's suggestion of a private syndicate of drug manufacturers, was referred to a subcommittee for further consideration.

### ROUTINE EXAMINATION OF THE HEALTHY

In his Alexander Black Memorial Lecture the first on that foundation, of which an abstract appeared in these columns, Dr C. E. Douglas gave an appreciation of the present position of the man in general practice, the family doctor showing that surrounding him were certain agencies all undeniably good in themselves but tending towards his gradual elimination as an important factor in the conduct of medicine. As a corrective of this undesirable tendency some suggestions were made as to lines of activity some remedial some preventive on which he might do sound work that none but he could approach. Of these a somewhat new idea is that indicated by the title of this note. At present no routine examination of the supposedly healthy is generally carried out. This statement requires some qualification for the school medical officer and the child welfare workers have been for years at work with excellent results. But these do not touch the sources of information at present contemplated. They show however the importance of such work and may be proposed to discuss briefly here its extension to the domain of family practice and the doing of it by the family doctor. It is a commonplace of vital statistics that illness is relatively a great deal too a small part of life and the routine examination of the apparently healthy the price of

life, say, beyond 45 years, is also of value. The sensible mother in the educated classes has for many years hitherto taken the family to the dentist whether they have toothache or not, and everyone of any long experience will agree that good has thus been effected. It is only a step from the dentist to the doctor, and she will soon be encouraged to take it. Thus, at the other end of life, interesting and important work has been carried out in the United States of America. Dr. Irving Fisher<sup>2</sup> shows that, beginning with Horace Debell of London,<sup>3</sup> who appears to have been in the sixties a voice crying in the wilderness, the idea of periodical medical examination as a preventive measure has been advocated from time to time, and now, particularly in the service of the Metropolitan Life Insurance Company of New York, results have been gained which will repay consideration. These results, he says, "were so astonishing that the actuarial department and the medical department refused to believe them until forced to do so by going over the records for themselves. The three departments then united in a report showing that, as a consequence of expending 60,000 dollars on medically examining 6,000 people within six years, the Metropolitan had gained, through premiums of people whose lives were extended, 120,000 dollars. In other words, this life insurance company had made 100 per cent on its investments." In this country the same idea is being worked out as a business proposition in two directions. There is a company which now undertakes the business of insurance against "doctors' bills"—the wording is perhaps unfortunate, though the principle of insurance against the risk of having to pay for medical attendance is a perfectly sound one to which little exception could be taken. But what concerns us more directly in this connexion is the scheme combined therewith in which it is proposed to carry out regular medical examinations under theegis of a commercial company. Reference to these projects has been made on several occasions in our columns, and we are not now greatly concerned with the precise terms under which such examinations are to be conducted, though these may in time require investigation. The point we would seek to make is that there appears to be no need for the intermediation of a business company at all. Suitable fees and something in the nature of a standardized examination if necessary, could be organized by the medical profession itself. It may be said that the Metropolitan Insurance Company of New York is an outside body, but the cases are not comparable, the company already has its policy-holders, and it is doing a mutual benefit in this work. But there is no need to restrict such examinations to the holders of life insurance policies. The ordinary man can get his own doctor to examine him at intervals without the formalities of applying to the companies. A word may be said about the possibilities opened up to the less scrupulous members either of the public or of the profession. Cases were not unknown years ago of elderly men making a proposal for life insurance solely in order to hear how they stood in point of health getting a thorough medical examination for nothing, and then declining to go on with the proposal. Moreover, anyone who has seen that amusing play *Dr. Arnold* will be aware of the opportunities placed in the hands of a commercialist who goes in for medicine. But when these possibilities have been discounted there remains the fact that the regular examination of the apparently healthy is coming upon us, that it had been adumbrated many years ago by some of our far-sighted predecessors, that it has been recognized by business men as a business proposition, and that, if the medical profession does not take the matter up and organize it, it will be worked by outside bodies to the exploitation of the great mass of the medical profession—the family doctors.

## LONDON'S MILK SUPPLY

The London citizen, as he sits at home enjoying his meals, knows little about the tremendous organization that is required to provide him with his food. Something of the romance of big business, together with the ease and comfort of modern travelling, was demonstrated on December 1st to a party of people who were the guests of the United Dairies Limited and the Great Western Railway Company. The occasion was a visit to the United Dairies depot at Wootton Bassett for the purpose of inspecting the company's new glass-lined tanks for conveying milk by rail. To this depot the milk is brought from farms in the surrounding area in ordinary ten-gallon churns. After samples have been taken for analysis the milk is poured into a trough and conducted to large coolers, where its temperature is reduced to 38° before passing into the tanks. These tanks are huge steel cylinders, to the interior of which a lining of glass enamel has been fused by heat. The cylinder is insulated with two inches of cork, which is protected by an outer covering of thin steel sheeting. The tank is mounted on a special truck made at the railway company's works. One truck conveys 3,000 gallons of milk—a quantity which used to require 300 churns and three milk vans—with a dead weight haulage of 22 tons instead of 80. The tank, when filled, is dispatched to the United Dairies distributing depot at Willesden, where the milk is unloaded at the rate of 150 gallons a minute, pasteurized, and bottled. From the railway point of view there is enormous saving, through the tank system, in sidings, vans, docks with appliances for loading and unloading, and staff. The advantages to the consumer are that the number of handlings of the milk is reduced from six or more to two. The cork-insulated cylinders maintain the temperature of the milk below 40° F during transit. The distributing centre is reached more quickly. When the tanks are empty they are rinsed with cold water, and the glass surface is thoroughly scrubbed. The interior of the cylinder is then sterilized by steam at a pressure of 50 lb to the square inch. The tank system of transport seems to mark a distinct advance in the milk supply of London, and is, of course, applicable to other large towns. A depot similar to that at Wootton Bassett has been opened at Cilybeby on the London, Midland, and Scottish Railway, and other centres are contemplated. The British railways carry 280,000,000 gallons of milk a year. Two-thirds of this is earned by the Great Western and the London, Midland, and Scottish lines and the United Dairies Willesden depot sends out 46,000 gallons of milk in bottles every day.

## THE HOSPITAL SAVING ASSOCIATION

The annual general meeting of the Hospital Saving Association, followed by a meeting of group representatives, was held at the Kingsway Hall on November 28th. The meeting of representatives was impressive, as there must have been at least 1,200 or 1,500 people present. In the absence of Viscount Hambledon through illness Sir Alan Anderson was in the chair. The annual report of the association showed that there were now 4,085 groups, consisting of 351,865 contributors, as compared with 3,182 groups, with 267,071 contributors, in 1926. The rate of annual income had increased from £150,000 to £216,000. During the year nearly 100,000 contributors and dependants, of whom 16,000 were in-patients, had been treated at voluntary hospitals on the list of the association. Direct payments to voluntary hospitals amounted to £103,000. Over £9,000 had been paid to rate-aided institutions, and £14,000 had been refunded to contributors treated in hospitals and rate-aided institutions which were non-co-operating. The magnitude of the work of the association was shown by the fact that last year's

<sup>2</sup> *Amer. Journ. of Public Health*, January, 1927.<sup>3</sup> *Lectures: Prevention by Medical Examination* 1861.

payments to the London Hospital alone amounted to £13,655. Sir Alan Anderson pointed out that the work of the association meant the collection of fourteen and a half million threepences, and that the circulation of the association's newspaper, the *Contributor*, now amounted to 75,000. The Lord Chancellor, Viscount Cave, recently elected vice-president of the association, who presided over the Commission on Voluntary Hospitals from which the idea of the association was derived, spoke of the improvement in the financial condition of the voluntary hospitals. He advocated closer co-operation between voluntary, special, and State-aided hospitals and convalescent homes and gained the applause of the meeting by asserting that the voluntary system must not be impaired, lest the welfare of the sick, the training of medical men and nurses, and the progress of study and research should be impeded. He considered that deductions from private employers was the easiest method of collecting the weekly threepences from the contributors. Professor Winifred Cillis enhanced the meeting by telling the stories of "the movable kidney and the loose liver" and of the "labour-saving device twilight sleep." She also impressed upon her audience the necessity for remembering that people should not be sent to hospital for illnesses which could quite well be treated by their general practitioners and that, even under the system of contributors' payments, the services of the medical staffs of voluntary hospitals were given free so that members of these staffs often put in the equivalent of two days' work a week without remuneration.

#### THE GENERAL MEDICAL COUNCIL'S INCOME TAX CASE

IN 1926 two cases of some importance to the medical profession were before the High Court. The Society for the Relief of Widows and Orphans of Medical Men and the Medical Charity for the Society for the West Riding of Yorkshire successfully defended an appeal brought by the Commissioners of Inland Revenue. In the two cases the main contentions of the Revenue were based on the fact that medical men were invited to qualify by subscription, and if Mr. Justice Rowlatt had accepted the view that that fact invalidated the claim to exemption on charitable grounds from income tax the decision would have seriously affected the valuable work being done by many similar societies. Recently the same judge has been called upon to decide another case in which the same statutory provisions were involved—we refer to the appeals taken by the General Medical Council and its English Branch Council. On this occasion Mr. Justice Rowlatt's decision is adverse to the professional interests; fortunately it seems less likely to have serious reactions on other cases. A detailed statement as to the constitution and activities of the Councils was, or came placed before the court but a very brief reminder of the main facts will suffice here. The Council was established under the Medical Act, 1858, and incorporated under Section (1) of the Medical Council Act of 1862 for the purpose of (a) keeping and publishing a register or qualified medical practitioners (b) of exercising oversight on medical studies and examinations, and (c) of publishing the *British Pharmacopoeia*. The exercise of these duties, together with the imposition of certain disabilities on unregistered persons were represented as operating—as clearly they do—for the public benefit and it was argued that the purposes of the Council were charitable and that the income received by the Council and devoted to the carrying out of those purposes was therefore exempt from income tax. One of the contentions of the Revenue authorities was in effect a transfer of emphasis to the other aspect of the Council's activities and it is concluded that the Councils were professional institutions whose activities were directed in the main to the interests of the medical profession, and therefore that

the claim to exemption as charitable bodies failed. Mr. Justice Rowlatt evidently attached some weight to the consideration that the Medical Act of 1858 did not seem to contemplate the holding of invested funds, but rather that all moneys received would be applied in meeting the expenses incurred in carrying out the provisions of that Act. He held that proof that the objects which the General Medical Council had been established by Parliament to achieve were for the good of the public was not of itself enough to bring the Council's income within the exemption. On the other hand, while no point out that it had been established in recorded decisions that societies for the benefit of professions were not societies with charitable objects, he agreed that this case was different in that the protection of the public was the main and not the secondary object of the General Medical Council. He laid, however, to keep in view the principle that "a body to be a charitable body must come within the analogy of the statute of 43 Elizabeth, cap. 4 which supplied the test." There was no authority for holding that a body such as the General Medical Council fell within that Act and the appeal therefore failed. We cannot but regret the decision. On the facts the Council appears to us as clearly entitled to exemption on grounds of equity and common sense as, for instance, an educational institution or a religious body, but in such matters the law, judicially interpreted, has the last word—even though it be taken from the dusty pages of an Elizabethan statute. One point may, however, be emphasized. It was admitted that in this case there was no trust for the improvement or the practice of medicine. In that respect, as, indeed, in some others, the position of the General Medical Council was vulnerable at a point in which many professional or semi-professional bodies are particularly strong. As we have said we regret the decision, we should regret it still more if through a failure to attach due importance to the special features of this case, the decision were to react unfairly on other deserving cases.

#### MENTAL HYGIENE.

THE National Council for Mental Hygiene, whose fourth annual report has just been issued, seeks to prosecute an extensive study of the causes of mental defect and disorder, to investigate the sociological background of these disabilities and to promote their prevention. The improvement of the mental health of the community involves a study of the social habits, of industrial life and of environment, and the enlightenment of the public in all matters which promote or militate against good mental health. The council aims at securing a more important position for the study of psychiatry in the medical curriculum, the closer association of psychiatry with general medicine, and the establishment of special clinics and out-patient departments for the early treatment of mental disorders. It seeks to raise the standard of care and treatment in the public mental hospitals, and to remove legal formalities which tend to postpone the effective treatment or cases of mental disorder in their early stages. By combating the prevailing ignorance and superstition regarding the true nature of mental disorder it hopes to aid in removing the stigma which handicaps the future welfare of those who have been thus afflicted. Though the measure of financial support received by the council has fallen considerably short of its expectations it can claim to have carried out a highly creditable amount of work both in the prevention and alleviation of mental illness since its inception four years ago. Among the urgent needs of the council are the appointment of a paid medical director, the publication of a monthly bulletin, the wide distribution of suitable literature, the giving of popular lectures on mental hygiene and the organization of research work. On the two short articles of very real interest appended to this

report, the first deals with the probable causes of mental disorder—a matter which was the subject of investigation by a special committee under the chairmanship of Dr W A Potts, which collected facts from a number of authorities with long experience. The committee insists on the recognition of the interrelationship of body and mind to such a degree that physical causes may be responsible for mental and bodily disorder of many kinds, whilst a psychological cause may be the most important factor in serious disturbance either of body or mind. The importance hitherto ascribed to heredity in the causation of mental disease is considered to have been exaggerated. As knowledge of causation increases, the share of heredity tends, in the committee's opinion, to become more and more restricted. "It is clear," it says, "that heredity is not the basic factor in the cause of all forms of mental abnormality, whether manifested as mental defect, delinquency, or mental disorder." Considerable stress is laid on the necessity of the study of mental hygiene in child life. Special dispositions and characteristics must be guided along healthy channels, the change of feelings and consequent change of behaviour at puberty must be realized and understood, and if necessary explained by the parents. The committee emphasizes the fact that it is the *fact*, and not the conduct, of life that is the dangerous factor. The committee "advocates no particular psychological creed, but would make available for the developing individual in the nursery, in the schoolroom, at the university, and in the responsibilities of adult life all that modern psychology can offer to help him in his difficulties."

#### THE GOLD-HEADED CANE AND WILLIAM MACMICHAEL

*The Gold-Headed Cane*, a gossipy record of certain prominent physicians of the seventeenth and eighteenth centuries, such as Radcliffe, Mord, Askew, the two Pitcairns, and Matthew Baillie, was first published anonymously on February 24th, 1827, and so deserves some centenary celebration such as Mr Herbert Spencer Robinson has provided in his bio-bibliographical article containing in account of its modest author, William Macmichael (1783-1839). Macmichael was an Oxford man, of Christ Church, a Radcliffe travelling Fellow, body physician for a year to the Marquess of Londonderry when British Ambassador at Vienna, and was a protégé of Sir Henry Hallford. Through Hallford's influence he became physician to the Middlesex Hospital, registrar of the Royal College of Physicians, physician extraordinary to George IV, and physician in ordinary to William IV, probably Macmichael obtained much private practice as his patron's substitute in those spacious times, when Hallford was President of the College for the "record" period of twenty-four years, from 1820 to 1844. The published works of Macmichael, who was also an anonymous contributor to *The Lives of British Physicians* (1830), which passed into a third edition, have been carefully collated by Mr Spencer Robinson, who has also been contributing to the same periodical interesting biographical sketches of the Harveian Orators. He has failed to discover a portrait or engraving of Macmichael, even in the collection of the College Anatomists. The first edition of *The Gold-Headed Cane* found in 1827, nine days after Macmichael was married when there'd a new and enlarged edition in the following year. The first edition is generally regarded as better healthy is commingled out by William Munk in 1884 many years ago by 1915, the first in America and the that it has been recognized by me on the title-page, was proposition, and that, if the method had in introduction take the matter up and organize by Dr F R Prebhard, outside bodies to the exploitation of edition. There had medical profession—the family doctor—the Johns Hopkins

Historical Club in 1906, in which Sir William Osler, Dr T McCrae, Cushing, and Fletcher took part (*Bull Johns Hopkins Hosp*, Baltimore, 1906, viii, 162-169). Mr Spencer Robinson's article is so fully documented that it will serve as a useful bibliographical source of reference to those interested in medical history, who, if they cannot pick up the earlier editions, would be well advised to secure the fifth edition, brought out in 1923 by Dr G C Perchev, before it, too, is obtainable only from second hand book-sellers.

#### MEDALS OF THE ROYAL SOCIETY

In compiling our list of medical recipients of the Royal Medal of the Royal Society the name of Professor William Kitchen Parker, F.R.S., was inadvertently omitted. Notwithstanding his enormous output of work in comparative anatomy, he was for the greater part of his life engaged in general practice, and is therefore an outstanding example of the possibility of combining most distinguished scientific observations with the quite different daily work of medical practice. Having held the qualification of L.S.A. since 1849, he was in 1873 admitted to the Membership of the Royal College of Surgeons after a mere formal examination, when he was appointed Hunterian lecturer on comparative anatomy. His work on the skull and on birds earned the warm praise of Huxley, and put the latter's conclusions beyond dispute, dealing the final death-blow to Owen's vertebral theory of the skull. In the notice in the *Dictionary of National Biography* Professor G B Howes writes "Such were his stores of anatomical knowledge that he was once known to speak for four hours continuously on the lower jawbone of the raven without saying anything that was other than valuable." It was a certain want of control and arrangement of this extraordinary store of facts which prevented his lectures being as successful as his knowledge should have made them. His contributions, often beautifully illustrated, to the *Philosophical Transactions* and to the proceedings of various scientific societies were well nigh innumerable.

#### TREATMENT OF DIFFICULT CHILDREN

UNDER the presidency of Sir Humphry Rolleston a council including physicians, magistrates, psychologists, social workers, and representatives of education authorities, universities, and Government departments, has been formed to promote the treatment of maladjusted, difficult, and delinquent children. The immediate aims of this body—to be known as the Child Guidance Council—may be summarized as the promotion of the establishment of child guidance clinics, the provision at universities of psychological instruction for social workers, demonstration of the need for such trained workers in existing clinics, and investigation of the various social and psychological problems involved. The children concerned are those whose conduct or progress at home or at school reveals abnormalities requiring special treatment, it is admitted that trouble often arises because such children react to unsatisfactory environments. It is hoped that a new child guidance clinic will be established in connexion with some university. Similar work has been in progress in the United States, where, in 1918, the late Mrs Harriman instituted a Commonwealth Fund, which has since been applied to various causes, irrespective of nationality. This fund will finance the Child Guidance Council until the autumn of 1928, and is contemplating the support of a child guidance clinic for three years. The fund has offered to pay the expenses of certain selected persons visiting similar institutions in the United States, and of five social workers willing to undertake a year's training there. It has also arranged for the secretary of the council to

## HEALTH OF THE SCHOOL CHILD

## HEALTH OF THE SCHOOL CHILD

[THE BRITISH  
MEDICAL JOURNAL]

**Sir George Newman's Report**  
THE annual report of the Chief Medical Officer to the Board of Education for the year 1926 appears in the form of a letter addressed to the Right Hon Lord Eustace Percy, the President of the Board of Education, by Sir George Newman, the Chief Medical Officer. This year the letter is shorter than usual, for much of the statistical matter commonly incorporated is now relegated to appendices. Some of the more general aspects of this report are dealt with in an annotation on page 1101. In this review the particular aspects of the year's work will be noted.

**Staff**  
There are now 1,223 doctors in the service of the various local education authorities, of these, 574 combine such duties with public health work, whilst 263 give their whole time to school work, and 386 are part-time officers. The equivalent in whole-time service is calculated as 611 officers, or one to 8,100 children. In addition there are 865 specialists employed in clinic work, of whom only 14 are whole-time, but of the school doctors some 548 do some form of specialist work. There are 591 school dentists, of whom 263 are whole-time. This works out at about one dentist to 13,500 children, which seems a small proportion considering the work that has to be done. The school nurses, part- or whole-time, number 4,779, which is estimated to be equivalent to 1,821 whole-time.

**Medical Inspection**  
The work of medical inspection, which is the basis of remedial work, is now judged to have reached a fairly complete stage. Children are examined periodically, at the ages of 5, 8, and 12 years, and at shorter intervals when defects are noted by teachers and others. It is doubted whether advantage would be gained by routine examinations at more frequent intervals, the great majority of serious defects, dental disease excepted, are believed to arise during the earlier years of life, and a large proportion are discovered at the first examination of the "entrants." More exact determination of physical efficiency will develop slowly as more satisfactory and reliable tests are devised, and as careful clinical study is applied to the physical condition of children of school age.

**The Results of Medical Inspection**  
There is again this year, as last, evidence that the physical condition of the entrants is better than in 1913. There is general improvement of the children at all ages in cleanliness, and the incidence of malnutrition at all ages is substantially less. No indication of general physical deterioration as a result of the coal strike of 1926 has been observed. The school medical officer for London is quoted:

"The survey of the statistics of medical inspections shows that while there is still much leeway to be made up, while still many children leave school with defects unremedied, there is year by year a notable improvement. This is especially marked in the case of personal hygiene, dental conditions and visual defect. It also shows that much of the defect is due to causes over which the schools can have no direct control, and that these causes operate most profoundly upon the infant in the pre-school years. The school medical service is a receiver of damaged goods and spends most of its time and energies in patching them up. What is now required is an intensification of social effort directed to the care of the infant in arms and the toddler before school age."

Summing up his evidence, Sir George concludes:  
"I do not think there can be much doubt that the physical condition and capacity of elementary school children throughout the country shows definite improvement (and not the reverse) during the last twenty years. From the data available it seems the child of today is stronger, taller and heavier than the child of 1907. He is a better nourished child. To what is this due? The medical care and supervision of the child before and during school life is producing its effect. Better nurture, the remedy of infective conditions which gravely impair physique, school meals, physical training more fresh air and improved school sanitation, can scarcely fail in the long run. The direct treatment of ailments and defects removes causes of weakness."

*The Health of the School Child. The Annual Report of the Chief Medical Officer of the Board of Education for the year 1926. His Majesty's Stationery Office 1927 (Pp 182, 1s 6d. net)*

less dental decay, less mouth breathing, fewer inflamed tonsils and glands, less tuberculosis and anaemia, a decline in severe rickets. There has also been great reform in the social life of the people, better housing conditions, better feeding, more cleanliness, better clothing and more fresh air. Heredity is a mighty factor in the building of physique, but the influence of heredity that runs it very close, and it has this advantage over heredity that we can control it directly. On the whole the best children physically are the best children mentally and a sound educational system is not dependent in childhood on improved methods of education only, but on a body nurture, on better feeding, on nervous control and regulation, on a steady growth of bone, muscle, and brain. We have been told on high authority that feeding wins more horse races than training. Feeding is equally important for the child."

**Nutrition**  
Little regard need be paid, in Sir George Newman's opinion, to the fashionable "stunts" of the present time, or of any time. Some advisers are all for wholemeal bread, others all against sugar, a third group concentrates on vitamins, and a fourth condemns oatmeal. The child needs all of these foods in a varied diet and in reasonable balance. The problem is not the relief of poverty, but the prevention of under-nourishment. The malnourished child is not necessarily the hungry child, nor yet one in a condition of starvation. Sometimes poverty is a direct cause, more often it is ignorance, unsatisfactory home conditions, lack of parental control, and absence of influences favourable to nutrition.

"It is careless mothering, ignorance of upbringing, and lack of nurture, rather than actual shortage of food, which results in the malnourished child. Insufficient sleep, chronic fatigue, absence of fresh air, and lack of exercise are exerting a very good influence day by day on the well-being of multitudes of children. Magnificent schemes and expensive staffs are of no avail if mothers and teachers neglect these simple matters. Disease is a cause of malnutrition, enlarged tonsils and adenoids, decayed teeth, congenital syphilis, tuberculosis and the like. Hence to provide more food or even better food is by no means the only answer to nutrition."

**Remedial Measures**  
Progress in school treatment schemes is noted during the year, but there is still room for improvement. Of 317 education authorities, 2 have no special provision for dealing with defects of vision, 14 all show some treatment for minor ailments, 23 have no special scheme, and 59 are without arrangements for the treatment of enlarged tonsils and adenoids. Orthopaedic treatment is undertaken in less than half the cases. In London there is, it is stated, a steady drift year by year of children from the voluntary hospitals to the treatment centres. This movement is accounted for partly by the popularity of the treatment centres, but still more by the policy of some of the hospitals which seek to relieve the pressure on their out-patient departments by diverting children who apply to them for treatment to the Council's centres.

An essential part of any treatment scheme is the establishment of measures for educating parents as to the need for treatment and to the still greater need for after care. Such measures include a service for the following up of cases at their homes by school nurses and Care Committees, and for educating the mothers by lectures, talks, leaflets, and personal guidance and counsel. There is evidence of this unceasing work. It is found that it is much harder to persuade parents to obtain dental treatment than any thing else. The treatment of squint is engaging the attention of education authorities to an increasing extent. Operative treatment, where necessary, is now provided by 37 authorities. Emphasis is laid on the fact that the earliest possible detection of the condition is essential if serious loss of vision is to be prevented, and satisfactory results are found to accrue from the notification and treatment of cases from infant welfare centres. Enlarged tonsils and adenoids are found in about 10 per cent of all school children, and in 5 per cent it is sufficiently severe to require operation. There is little doubt that in the majority of cases the condition arises before school age. In London, of 10,168 children referred for treatment, 5,724 were entrant infants "amongst whom the greatest proportion of diseased throat conditions is always found." Hospitals are becoming more used for operative treatment than clinics, probably owing to the

increasing recognition of the importance of inpatient reception and after-treatment. Mr. Latham records the results obtained by operation. Dermal was cured in 51 cases out of 74 (68 per cent); otitis in 23 out of 33 (70 per cent), and empyema in 27 out of 46 (59 per cent).

(To be continued.)

## Union of South Africa.

[FROM OUR CORRESPONDENT IN PRETORIA.]

MOQUITO SURVEY OF SOUTH AFRICA. Information regarding the distribution of mosquitos in South Africa is still remarkably scant. A few investigators have at various times done isolated and purely localized work but until recently nothing in the nature of a general survey has been attempted. This deficiency in our knowledge of the mosquito fauna is regrettable in view of the carrying by these insects of malaria and dengue to man in certain parts of the country. From the veterinary point of view too definite knowledge is necessary, as culicines are suspected of conveying horse sickness which annually causes tremendous loss to the country and has rendered horse breeding in otherwise very suitable districts economically impracticable. Knowledge of the habits of these carriers of disease is necessary so that destruction may be carried out at their most vulnerable periods. In most parts of this country there is a periodical seasonal diminution in the numbers of mosquitos. Destruction of early broods would therefore yield beneficial results later in the season. The natural tendency however is to introduce anti-mosquito measures only when the insects are most prevalent. The desirability of having accurate information has long been realized by the health authorities of the Union, but it has only recently become practicable to commence a systematic survey. Early last year the South African Institute for Medical Research began field work in the Northern Transvaal. While this survey was in progress, agrarian plinters in Zululand became disturbed at the prevalence of malaria on their plantations and the Union health department decided that an anopheline survey of this part of the country should be undertaken without delay in view of the recent railway extensions and the development of cotton growing and other agricultural progress. A conference attended by representatives of the health department, South African Institute for Medical Research and the Veterinary Research Division discussed the practicability of co-operation in a general survey of all blood-sucking flies throughout the country. The survey has however had to be limited to anophelines and culicines—the latter mainly for the purposes of the agricultural department. It is being carried out by the entomological department of the South African Institute for Medical Research. A report of the survey of parts of the Northern Transvaal and of the coastal belt of Zululand by A. Ingram M.D. medical entomologist to the institute and his assistant B. de Meillon B.Sc. appears in the latest publication of the institute (No. 100, vol. iv). It is a valuable contribution to the problem of dealing with the insect carriers of human and animal diseases in this country.

### Northern Transvaal

The preliminary survey of parts of the Northern Transvaal commenced in January 1926 was concerned with the determination of the chief malaria vectors and the location of the haunts of these larvae. A few culicine mosquitos were also collected. The survey was carried out in the districts of Rustenburg, Waterberg and Zoutpansberg. The parts visited are all situated at an altitude of about 4000 feet above sea level with an average annual rainfall varying between 25 inches in Waterberg and 52 inches in parts of Zoutpansberg. Approximately 90 per cent of this rainfall during the summer months, October to March. These records are such that it would seem that malaria in these parts assumes epidemic form at fairly regular intervals resembling the outbreaks in the Punjab described by Carter. In these intervals it would appear that the resistance established by the previous epidemic is sufficiently

reduced to allow of the disease assuming epidemic form in a season in which an excessive rainfall has occurred in the pre-malarial period. Here, as in the Punjab, excessive rainfall will apparently not result in an epidemic in a population which has had its resistance raised by an epidemic occurring the previous year. The investigators suggest that given an accumulation of cases of enlarged spleen in the malarious districts and a record of the rainfall during the pre-epidemic period (that is October to January) it ought to be possible to forecast the occurrence of malaria in epidemic form as is done for the Punjab in India. The anophelines collected during the Northern Transvaal survey were *A. mauritanicus*, *A. squamosus*, *A. gambiae* (costalis), *A. pretoriensis*, *A. ruppesi*, *A. funestus*, *A. natalensis* (aucto. quamvis), *A. transvaalensis*, *A. maculipalpis*, *A. rhodesiensis* and *A. theileri*, *A. cinereus*, and *A. longipalpis*. Adult specimens were collected where seen, but the majority of the anophelines obtained were reared from larvae found in bodies of water in the different districts. The recognized carriers of malaria in South Africa are *A. funestus* and *A. gambiae* (costalis). No larvae of either of these were however found in the Waterberg during September and the first fortnight of October. It would appear therefore that active breeding of these two anophelines does not occur in the winter and spring. Further, no adults were found in any of the houses inspected. If these two mosquitos are the carriers of malaria in the Waterberg—as they certainly are in other parts of Africa—it is probable that hibernation of the adult takes place out of doors amongst the grasses, reeds and shrubs in the vicinity of the watercourses. The investigators strongly recommend the burning of the vegetation in the marshes and along the banks of the rivers in winter.

### Zululand

The Zululand survey was commenced at the end of January of this year. Most of the time was spent in collecting larvae and in examining the conditions and surroundings of the various waters in which they were found. Zululand is situated between latitudes 27° and 28° south. The coastal belt is flat but inland the rise is rapid to heights of from 2000 to 5000 feet above the sea. The belt is intersected by numerous rivers rising in the highlands and heavy floods are liable to occur in the rainy season owing to the water being impeded in its course to the sea by sandlocked lagoons. At all times there are considerable stretches of marshy ground adjacent to the rivers as they traverse the coastal belt. The average annual rainfall is about 38 inches of which some 80 per cent falls in the summer months between October and May—January and February being the wettest months. During the recent outbreak of dengue fever in Durban some unusual breeding places were ascribed to its vector *Aedes (Stegomyia) argenteus*. The present investigators found no reason to differ from Carter who states that this mosquito in its larval stage is not found in marshes, sluggish streams or in any collection of water where at the water's edge there is nothing but mud. Larvae of this mosquito were found in house tanks. Here as elsewhere in South Africa the two principal mosquito carriers of malaria were found to be *Anopheles gambiae* (costalis) and *Anopheles funestus*. The former was however found in this survey to be much more numerous than the latter and it is probably the chief carrier of malaria in Zululand. It appears to show a seasonal variation in numbers. A record of its prevalence during each month of the year in the malarial districts of Zululand is therefore desirable. Much might be done to reduce the output of anophelines by the periodical removal of floating water plants which afford shade and protection to the larvae. This and clearing of grass and reeds in and about pools, and the draining of the banks or streams in the neighbourhood of houses and native villages is advocated by the surveyors. Financial reasons will of necessity limit the extent of such measures but they should be carried out within a radius of half a mile or slightly less. Segregation of natives is enforced in Zululand as in other parts of the Union. Zululand where the agent as well as the material suffers from malaria and is a potential carrier of malaria collected at M'rubatubi appear to indicate that the

indigenous race of Zululand has established a certain degree of immunity is compared with the imported races—a fact which may be made use of by the Public Health Department in the future recruiting of labour for the industries of Zululand.

#### THE SOUTH AFRICAN INSTITUTE FOR MEDICAL RESEARCH, JOHANNESBURG

The annual report of the director of the South African Institute for Medical Research for the year ended December 31st, 1926, was published on November 3rd. During the year Dr W. Watkins-Pitchford, who had held the appointment of director of the institute since its inception in 1912, retired because of ill health, and was succeeded by Sir Spencer Lister. The institute is divided into a research and a routine division. Much of the work of the research division reviewed in this report has already been described in these letters. The work included investigations into plague, tuberculosis, heart-stroke in deep-level mines, effects of inhalation of asbestos and other dusts, bionomics of the ectoparasites of rodents, bilharziasis, and such biochemical research as the steady growth of the routine work in the department of biochemistry has permitted.

#### Plague Infection

To ascertain how plague infection is kept alive among gerbilles during off seasons between epizootics a series of experiments was carried out in fenced-off runs on the veld. It was found that plague-infected skins could live without any hosts for periods up to three and possibly even four months, and still retain the power of infecting fresh hosts. Such longevity, taken in conjunction with the known habit of the gerbille of visiting every burrow in its neighbourhood, may explain how plague infection can be kept going in a scanty rodent population until conditions become favourable for the occurrence of an epizootic. "Tiger River disease," which was found occurring naturally among veld rodents in 1925, was not again met with in the field. Experiments, however, were made with cultures of the causative organism to ascertain its possible use as a virus for the destruction of gerbilles. Food containing the bacilli was found to be very fatal to such rodents; as actually to it, the virus being at least as efficacious as any ordinary poison which had been employed, and some evidence was obtained that the disease had established itself as an enzootic infection. The virus would probably be useful in a gerbille-infested area in which a plague wave was due. A Tiger River disease wave might be made to anticipate and even prevent a plague epizootic. The causative organism of this disease was independently and previously discovered at Cambridge, England, by Dr E. G. Murray, as the cause of an epizootic amongst rabbits, and named by him *Bacterium monocytogenes*, from its unique character of eliciting a large mononuclear response in the circulating blood of infected animals.

#### Heat-stroke in Deep-level Mines

As a result of a series of deaths from heat-stroke in the deep levels of certain gold mines, Dr A. Mavrogordato, Industrial Hygiene Research Fellow, and Dr H. Prior, Government mining engineer, engaged on an inquiry into deep-level mining in relation to high wet-bulb temperatures. The results of their work were communicated to the South African Institute of Engineers, in whose journal it was published (vol. xvi, February, 1927). It was found that many of the working places in the mines had a wet-bulb temperature of 86° F., the level above which temperature control tends to break down in European engaged in physical labour. Cooling of working places presents considerable difficulties. As they are constantly shifting, in which has been cooled at a fixed point would warm up too rapidly on its way to the more distant working places for a useful fall in temperature to be secured. It was urged that attempts should be made to increase the difference between the wet- and the dry-bulb readings, which was found rarely to exceed 2° F. It was suggested that this might be done by delivering air in by pipes to the working places, and by attempting to reduce the amount of water used in dust laying.

#### The Routine Division

In this division 65,980 investigations were made during the year—an increase of 13,136 over 1925. This increase was largely in investigations of a bacteriological and serological nature, associated with the diagnosis of specified diseases, particularly tuberculosis, syphilis, typhoid fever, and gonorrhoea. In the biochemical department there was a fall of 627 in the number of examinations as compared with 1925, due chiefly to a decrease in the requests for blood sugar estimations. As the number of patients in the two years was almost identical, the decrease in sugar estimations would appear to indicate a growing facility in the use of insulin, and the consequent reduction in the need for laboratory control once the patient's equilibrium has been established.

Hookworm infection with *Ancylostoma duodenale* was found in miners whose blood also showed a marked eosinophilia. Hydatid infection was confirmed microscopically in eight subjects. In four cases the application of the Cason or hydatid skin test gave a positive reaction which was confirmed on operation, but on two occasions operation following a positive skin reaction revealed the presence of an amoebic abscess in the liver. The reaction is being further tested.

The number of rodents sent in for plague examination was 2,234. Of these the largest number (2,138) were received from the Johannesburg municipality, all of which proved negative on examination for the presence of *B. pestis*. Of the remainder, 9 veld rodents were found harbouring the bacillus.

Evidence of schistosome infection was found in 122 of the specimens, chiefly urinary, of the 432 submitted for examination. *S. haematobium* is the trematode whose ova were most frequently derived from the urinary tract, *S. spindalis* having been found in the urine of only one patient. On six occasions the intestinal form of the disease was confirmed by the finding of ova of *S. mansoni* in the faeces. The wider application in general practice of the Wassermann test is indicated by the marked increase of specimens examined. During the year 10,367 examinations, mostly serological, were made, positive results being obtained in 29 per cent of the specimens received. To ascertain the incidence of specific infection among native mine workers an extensive investigation in co-operation with the Witwatersrand Native Labour Association has been begun. The blood from over 1,000 unselected natives is being subjected to the Wassermann test. Interesting and reliable data are expected from the results of this investigation. The increased activity in the investigation of tuberculosis is partly reflected in a large increase of specimens, chiefly sputums, received for examination, 18,780 specimens were received. The Weil-Felix test for typhus was applied with 1,120 serums—a decrease of 233 compared with the previous year. During the year 1,260 autogenous vaccines were prepared, and numerous stock vaccines and serums were issued.

## India.

#### MEDICAL TREATMENT IN THE NORTH-WEST FRONTIER PROVINCE

The number of patients treated in all classes of hospitals and dispensaries in the North-West Frontier Province has increased considerably, the figures being 1,127,268 in 1926 and 1,078,443 in 1925. The number of surgical operations was also much larger, and there was a fall in the death rate in these patients in comparison with the two previous years. There was no such epidemic of cholera as that of 1925, and an outbreak of plague in Mardan was practically confined to that division. The number of malarial patients increased from 43,967 in 1925 to 46,441 in 1926, but the number of deaths fell. The largest number of major operations was performed in the Lzerton Hospital, Peshawar, the Binnu Mission Hospital coming second. The health of the South Waziristan Scouts and the Tachi Scouts continues to improve. The total number of hospitals and dispensaries working during 1926 was eighty.

six-one more than in the previous year. The establishment of two civil dispensaries has been sanctioned and the Provincial Dns Training Centre in Dera Ismail Khan has been completed.

#### CHOLERA IN MADRAS

During 1926 the field work in Madras in connexion with the control of cholera by preventive inoculation and treatment of early cases was continued, with the help of a further grant from the Indian Research Fund Association. In his annual report Lieut Colonel A. J. H. Russell, I.M.S., director of public health for Madras states that some parts of the Presidency continue to be heavily infected with cholera, but this made it possible to carry on immunization experiments, both with anti-cholera vaccine and with the Besredka cholera bio-vaccine which is given by the mouth. In order to test the comparative value of these vaccines different groups of individuals in infected villages, and in particular in the contacts of cholera cases, were treated, members of the population who refused protection by either vaccine served as controls. Up to September, 1926, the number of cases analysed was 20,000 and the results indicated that anti-cholera vaccine conferred a very considerable degree of protection, the case rate and mortality rate being, respectively, 3.3 and 1.1 per cent as compared with 18.1 and 6.2 per cent in unprotected group. Although too few patients were treated by Besredka's bio-vaccine to permit definite conclusions to be drawn, the figures indicated that this vaccine also conferred a high degree of immunity, the treatment or control was continued during the winter and it is hoped that the statistics now becoming available may make it possible to form a definite opinion. This work was undertaken by the Indian Research Fund Association at the suggestion of the health section of the League of Nations. It is stated that the villagers are much more willing to submit to inoculation than to swallow the bio-vaccine tablets. Colonel Russell thinks that whenever the purity of rural water supplies is at all doubtful the widest use of a preventive vaccine would seem to be indicated. It is hoped that it may be possible to provide free supplies of anti-cholera vaccine to all local bodies. Acknowledgement is made of the assistance rendered by the Indian Research Fund Association, which has again sanctioned a grant for the employment of a statistical assistant to continue the epidemiological studies on cholera. Papers on this subject have been published in the *Indian Journal of Medical Research*. The hope is also expressed that it may be possible to forecast cholera epidemics two or three months before they occur, the method employed has been tested in other provinces of India as well as in Madras, and has not so far failed in any case. A full report is promised before long on the geographical survey of cholera in the Presidency.

#### PROGRESS OF VACCINATION IN BENGAL

In a triennial report on vaccination in Bengal for the years 1923-26 Dr M. L. Sufi, assistant director of public health commends the adoption of free vaccination by house to house visitation by paid vaccinators in place of the old method of licensing such practitioners. This together with the increased activities of local bodies and the financial help afforded by the Government, enabled the district boards to oppose successfully the quinquennial onslaught of small pox, which, in consequence, exacted a smaller toll of lives than in the previous quinquennium. Evidence of the arousing of the sanitary conscience of the people generally is afforded by the gradual increase in the number of vaccinations. Dr Sufi suggests that if the district boards and other local authorities could maintain a large enough staff of qualified vaccinators and supervisors, small pox epidemics would be abolished. In cases where persuasion has failed, strict legal enforcement of the Vaccination Acts to almost the whole of Bengal with the preparation of lists of unprotected persons and early notification of the first cases of small pox, would be valuable as subsidiary factors in the reduction of this disease. In Calcutta a smaller number of vaccinations is recorded owing to the fact that a very large number of people were treated during the previous year in anticipation of the quinquennial epidemic. There has been a

great improvement in the number of vaccinations of persons employed in the tea gardens during the year. Lanolin lymph is now being replaced by the more popular glycerin lymph. The quinquennial outbreak of small pox which started in December, 1924, and continued during the following year, exacted a heavy death toll owing to the prevalence of the disease during the months of April and May, 1925. The outbreak, being of a very severe form, was mostly confined to Calcutta and the neighbouring districts, at least in its early stage. During the previous quinquennium it extended over the Presidency. The spread of the disease in one district was due largely to a constant influx of people from Bhutan, Sikkim, and Tibet. In other areas the outbreak was started by infected persons in Calcutta and Howrah. A timely intensive campaign of vaccination and revaccination cut short the spread of the epidemic to outlying areas. Dr Sufi praises the activities in this connexion of several local authorities, and urges the appointment in each division of a medical graduate possessing the diploma in public health, and a special knowledge of bacteriological work. He regrets that during last year only about 270 per 1,000 of the estimated number of infants were successfully vaccinated, he attributes this to laxity in the enforcement of the provisions of the compulsory Act. Vaccination or contact has been neglected, and the failure of the law to help the local sanitary authorities in undertaking such duties measures has been the subject of adverse comment by some of the district health officers.

## England and Wales.

#### SIR DAVID DRUMMOND

In celebration of fifty years' service given by him to the University of Durham College of Medicine, Sir David Drummond, C.B.T., M.D., Past President of the British Medical Association, was presented at Newcastle on December 1st with his portrait in oils. The painting is by Mr R. G. Eves and shows Sir David in the robes of vice-chancellor of the University. The presentation was made by Mr P. G. C. Mortimer, chairman of the governor who recalled briefly Sir David Drummond's distinguished career since his appointment as lecturer on therapeutics in 1876. Warm tributes were paid also by Professor Thomas Beattie who said that as a teacher of medicine and pathology he had earned the lifelong gratitude of a host of practitioners and by Sir Robert Bolam who recalled his original work in connexion with empyema, neuritis and general paresis. In returning thanks for the honour conferred upon him Sir David Drummond said that it had been his good fortune to be appointed lecturer in the college just at a time when there was a revival in the teaching of clinical medicine when Byrom Bramwell and Rutherford Morrison were putting life into bedside teaching at Newcastle. Since those days the college had advanced and developed enormously, and now stood among the foremost medical schools in the country. He then invited the College of Medicine to accept the painting if a place could be found for it among the portraits of those who had given of their best and devoted their lives to it and Sir Thomas Oliver as president of the college gratefully accepted.

#### NEW GENERAL HOSPITAL FOR MIDDLESEX

A new hospital at Edgware, Middlesex built by the Hendon board of guardians was opened by the Minister of Health on December 5th. The Edgware Hospital (as it is called, after the name of the old infirmary) has been constructed on most modern hospital lines in grounds of twenty acres. It contains 175 beds, but can be extended to provide three times that number. It includes medical, surgical and maternity wards, an isolation annex, administration, receiving, operating and pathological blocks and a separate building to serve as a home for the matron and forty sisters and nurses. On the south side of each ward is a paved terrace for beds. The hospital is intended only for the treatment of acute cases, chronic cases will continue to be treated at the old infirmary. Mr Neville

Chamberlain, opening the building, said that he greatly appreciated the long and carefully directed efforts of the guardians of the Hendon Union in making this noteworthy contribution to the hospital accommodation of the district. Although the prevention of disease was the objective of much effort, treatment—especially of the institutional kind—would remain necessary, it was constantly changing, developing, and branching out in new directions. In a former time medical treatment, while formidable enough for the patient, was a very simple affair, the result of strictly limited resources and ideas. Henry VIII was crippled for years, and ultimately died, on account of an ulcer of the leg for which the medical science of his time could do nothing. Edward VI suffered from what was apparently consumption, but the attendance of the royal physician and of an Oxford professor was unavailing, and finally a female quack was called in, who administered such drastic remedies that the hair and nails of the poor youth were destroyed. Charles II was tortured on his death-bed by fourteen doctors, who dosed him morning and night with concoctions, the last harmful of which was forty drops of the spirit of the human skull. All that belonged to a distant past, but it was only within quite recent years—in only the Listerian epoch—that the great advances in medicine and surgery had been made. With these had come specialization and the need for special equipment, in order to get the best modern treatment in increasing number of patients had to enter an institution where medical skill and trained nursing could have sufficient scope in suitable surroundings. Another question of importance from the point of view of hospital provision was that the population was not only increasing but becoming more mobile. He was told that in the neighbourhood of the hospital the Witting estate of the London County Council was extending by a thousand new houses a year, and during the last few years there had been an influx of population into the area of the Hendon Union of many thousand people. New houses introduced complications, such as the need for fresh means of transit, additional schools, and extended hospital accommodation. In Middlesex the voluntary hospital accommodation in proportion to the population was considerably below the average for the whole of London, or even for the country, a debt of gratitude was due therefore to the Hendon guardians, who had provided this first-rate general hospital, which, perhaps, would not always be confined to the treatment of the sick poor. The old idea that the rich could be treated in their own homes, the poor in voluntary hospitals, that those who were neither rich nor poor must never be ill because there was no hospital provision for them, and that for the proper, sane or insane, curable or incurable, there was reserved the workhouse infirmary, was passing away, it was felt to-day that there was no class in the community who should be excluded from hospital treatment. The fact that this new institution was called a hospital and not an infirmary was significant of the tendency for these old distinctions to disappear. A time was coming when every hospital, whether voluntary, municipal, or Poor Law, would play its part in the general scheme of institutional treatment which should be sufficient to provide for the needs of the population in the area, when that time came this new hospital would be ready to make an important contribution to national health. Sir PHILIP CUNLIFFE-LISTER, President of the Board of Trade who is M.P. for Hendon, paid a special tribute to the honorary physician of the hospital, Dr Alexander Fiddler, to whose persevering effort, extending over many years, as the promoter of the board of guardians in this matter, the success of the scheme was very largely due.

#### LONDON SCHOOL OF MEDICINE FOR WOMEN

The annual dinner of the London (Royal Free Hospital) School of Medicine for Women took place at the Savoy Hotel on December 1st under the chairmanship of Dr A. G. Phear, C.B., senior physician to the hospital. Among the company of nearly four hundred were the Dean (Lady Bissett), Sir James and Lady Bell, Sir William Beveridge, K.C.B. (Vice-Chancellor of the University of London), Sir Hiram Greenwood, Sir Milson Ross, Lord Riddell, Dame Mary Schreber, and Sir StClair Thomson.

Sir William Beveridge, in proposing the health of the school and hospital, said that there was no medical school in the University of London to whose dinner he more gladly came, for by ties of locality and interest this school was more completely and intimately a part of the University than almost any other. It was also the pioneer school in the training of women for the noblest of all professions. Speaking of the Bloomsbury site, the Vice-Chancellor said that he looked forward to the portion of Bloomsbury acquired by the University of London as the future academic centre of London, as definitely as Whitehall was the centre of government or the City the centre of commerce. The chairman, in responding to the toast, gave an outline of the more important events which had taken place during the year. He made a special allusion to the late chairman of the hospital, Mr. Lengton, in whose death the hospital had sustained a severe loss, for the work of that institution and everything connected with it had been the absorbing interest of his life. The hospital and school had suffered grievously in this way, for the removal of the personality of the late Dean (Dame Louisa Aldrich-Blake) was still fresh in all their minds. Among the stiff changes was the appointment of Miss M. Wade, F.R.C.S., a past student of the school, to fill the vacancy caused by the retirement of Dr. Giansou. The newest acquisitions on the staff were Mr. Paul Jenner Verrall and Dr. Neill Hobhouse. Since Her Majesty opened the new children's ward during the past summer, Dr. Hazel Chodak Gregory had become the chief of that department. The school was growing from strength to strength, both in learning and athletics, and without attempting to enumerate its successes he owed to some bewilderment at the almost tedious brilliancy of its examination results. Miss Dearmley proposed the health of the guests, to which responses were forthcoming from Sir StClair Thomson, with his unfailing budget of humorous stories, and from Lady Greenwood. A former student, Miss Janet K. Aitken, proposed the health of the chairman, remarking that Dr. Phear had first and foremost taught his students medicine. After the speeches the company broke up for dancing.

#### AN INDUSTRIAL MUSEUM

Before the war the Home Office had in view the formation of an industrial museum as a permanent exhibition of methods, arrangements, and appliances for securing the safety, health, and welfare of workers in factories and industrial processes. The museum has now materialized, and, after a private view by the King and Queen, was opened to the public on December 5th. It is a two-storied building in Horseferry Road, Westminster. On the ground floor machinery for drilling, printing, cotton carding, laundering, and calendering is shown, in which are many devices for protecting dangerous portions of the machinery, and for instantaneous stopping if a worker is caught in the machine. In the basement there are exhibits showing the principles of efficient lighting in industrial work, and systems of ventilation illustrating the difference between good and bad methods. The portion of the exhibition of most interest to the medical profession is in the gallery on the first floor. Here are shown the results and methods of prevention of such industrial diseases as anthrax, lead poisoning, silicosis, and dermatitis caused by paraffin, benzol, mercury, chrome, sugar, and other substances. This section is illustrated by a series of excellent wax models of skin eruptions, for the preparation of which the authorities were compelled to seek the assistance of craftsmen in Budapest. There are photographs showing such protective measures as washing arrangements and respiratory masks now used in lead and other industries under Home Office regulations. The unbreakable crockery was an attractive and artistic exhibit, but the price of the ware might raise doubts as to its economy in use. The exhibition is interesting in its display of ingenuity in invention, and useful in showing the extent to which the worker is now protected by regulation—very often from his own failure to appreciate the existence of danger. But we hope the object in view was not merely, as we heard suggested, that the worker might learn about the conditions which he has a right to expect in the factory he works in. After

all, there is something in the motto which the late Canon Barnett put in the Towns' institution: "Duties, not rights."

#### CENTRAL MIDWIVES BOARD

The Central Midwives Board for England and Wales met on December 1st when it considered two resolutions it had received as to the form of ante-natal record issued for the use of midwife. The first was from the County Council Association, which expressed its concurrence with the view of the Wilts Public Health Committee that, while ante-natal examination is valuable, more harm than good would be done by an attempt to carry out the work in all cases in the manner suggested in the form of record. The Board agreed to consider the point. The other resolution was from the Maternity and Child Welfare Subcommittee of the British Medical Association, which was as follows:

1. That it is undesirable that there should be assigned to midwife any duties which can only be properly carried out by a duly qualified medical practitioner.
2. That if the ante-natal record form issued by the Central Midwives Board is filled in by a midwife the implication is that the cases referred to is classified as being all with regard to any conditions not noted or even a condition which may be imperfectly noted and therefore does not require the attention of a medical practitioner and that such a position is unsatisfactory from the point of view of the patient.
3. That all pregnant women should be examined during pregnancy by a fully qualified medical practitioner.

The Board agreed with Clause 1. As to Clause 2, the meaning of which the Board considered obscure, it referred the British Medical Association to Rule L 20. As regarded Clause 3 the suggestion was agreed to be desirable if practicable.

#### CHILD DEFECTIVE

At the end of November a conference was held in London to consider the development of special schools for physically and mentally defective children. It was held under the auspices of the National Special Schools Union, a body founded about a quarter of a century ago to advance the education of such children and to enlist the sympathy of the public on their behalf. Only from 2 to 5 per cent—in London 2 per cent—of the school population come within the fold of the special school, but as the president of the union Mr. Albert H. Hill pointed out the importance of the questions involved in the care and management of these children is out of all proportion to the total number of them. Lord Birmaham presided at the opening session and the London County Council, which daily employs a fleet of seventy special ambulances to carry 10,000 such children to and from school gave it a special blessing. The Hon. Lady Lawrence, chairman of the Special Services Subcommittee of the Council, received the delegates at the Council's Hall where an exhibition of the educational apparatus used at special schools was arranged, and the handwork of some of the children was on view. The conference lasted three days and discussions were held on the after-care of the physically defective, the function and the future of day special schools, the bearing of mental deficiency on crime and the treatment of the rheumatic child. Miss Martineau, J.P., chairman of the Special Schools Committee of Birmingham expressed the opinion that some children were admitted to special schools whose place ought to be in the dull and backward classes in elementary schools and that some of too low a grade were sent to special schools for which they were not suited. Dr. Acton-Davis, on the other hand, argued that milder cases ought to be admitted to special schools and admitted earlier. The subject of crime and mental deficiency was broached by Dr. J. J. Linds, governor of H.M. Prison for Boys, Wandsworth, who said that 5 per cent of the remands sent to that institution were certifiable under the Mental Deficiency Act. Every child in a special school should be considered separately, and his educational treatment modified in accordance with his special need. The first signs of delinquency should be recognized in order that they might be suitably treated, and special care should be given to delinquents during the adolescent period which is a transition to the normal child, as the period of greatest crime and emotional instability. Dr. Dimmock Fordyce, certifying officer to the Liverpool

education authority, spoke in favour of special residential schools for the rheumatic child. He thought that six months might be taken as about the desirable limit for rheumatic children to remain in hospital even in the excellent country hospitals with schools attached and that afterwards—or in the case of children who had never received hospital treatment for active rheumatism, when they were discovered to be sufferers—they should be sent to a residential institution primarily a school and only incidentally a place of treatment, for eighteen months or longer. Only by such means could rheumatic children, particularly when coming from a slum environment, be reasonably dealt with educationally and medically. He reminded the conference that rheumatic children could be reared to take their place amongst the world's best workers—that they were potentially energetic and capable citizens—and that indeed in many respects the rheumatic diathesis appeared to be the sign of civilization.

#### THE COMBATING OF DIPHTHERIA IN LONDON

At the meeting of the London County Council on November 29th a long report was submitted by the Public Health Committee on the question of the Schick test and active immunization against diphtheria. The committee quoted extensively from Dr. Graham Forbes's report issued under the auspices of the Medical Research Council in the early part of the year (*British Medical Journal*, May 21st, page 925) but added that as regards actual experience of active immunization in this country where it had been adopted in a particular area the number of children immunized in proportion to the number of susceptibles was so small and the period during which this preventive measure had been employed so short that no marked variation in incidence was to be expected although there was evidence that where the population or institutions, such as staffs of fever hospitals had been immunized there was a marked diminution in incidence. That there was need for caution in relying on the rather diminution in the prevalence of the disease in New York in 1924-26 to active immunization alone was clear from the fact that during the first six months of 1927 there had been a notable rise both in incidence and mortality in New York City. The committee felt that north as yet had active immunization been carried out with such complications as to render it impossible to draw any conclusions and certain conclusions as to the incidence of diphtheria upon any given community. Having regard to all the evidence so far available however, there can be no reasonable doubt that active immunization is now regarded by many prominent members of the medical profession as a valuable preventive measure.

London (the L.C.C. report continued) held an unequivalently position both in Great Britain and the whole of Europe in respect to the incidence of and the mortality from diphtheria. From 1911 to 1925 the average annual rate was higher than in any other large city in Great Britain though it was possible that these figures were exaggerated by the fact that many doubtful cases were notified on bacteriological evidence alone. Bacteriological facilities for such diagnoses being more readily available in London than elsewhere, and that in clinical diphtheria London did not compare as badly with other places as might be supposed. The average death rate during the period just mentioned placed London fourth amongst the large towns of Great Britain but in 1924—the year for which figures were available—the death rate in London from diphtheria was preceded only by that of Manchester and Portsmouth amongst the capital towns. Further, it was pointed out that the problem of immunization in London is a serious one. The Metropolitan Council has established a number of centres with the Schick test. The evidence to which the committee referred was that the death rate in the six boroughs of the City of London was 1.1 per 100,000 of the population, and that in the other five boroughs it was 0.8 per 100,000. The parents of the children who had been immunized in the City of London were 1.1 per 100,000, and in the other five boroughs it was 0.8 per 100,000. The committee suggested that the Schick test should be extended to all parents of children under 15 years of age, and that the opportunity of obtaining the Schick test should be given to all parents of children under 15 years of age.

and been considered that as an experiment, in connexion with selected schools at which diphtheria incidence was high, facilities should be provided for the contacts of diphtheria cases to be inoculated as a preventive measure, but the committee considered that if isolated schools were selected it would be doubtful whether any sound conclusion could be drawn as regards incidence, owing to the fluidity of the school population, moreover, in the present state of public knowledge, the proportion of parental consents would not be high. In Holborn, Deptford, and Camberwell the school organization had already been used for the distribution of leaflets on the Schick test. The conclusion of the committee was that measures for the prevention of the spread of diphtheria were primarily the duty of the borough councils, and that so far as the county council was concerned, it would be premature to introduce any measure of active immunization among school children, even on a limited scale, until further experience had been gained. A further report is to be made in a year's time.

It is evident that the two main considerations which have led the Public Health Committee to this decision are (1) the magnitude of the Council's responsibilities, with the fact that the greater the proposed sphere of action for a relatively new procedure the more needful it is that its efficacy shall not only be proved to the expert but demonstrable beyond all civil to the laity, and (2) the fact that the metropolitan borough councils are really the responsible authorities in this matter concerned as they are with the prevention of infectious disease. The six councils named which have already started centres for immunization are the Westminster City Council and the borough councils of Bittern, Camberwell, Deptford, Hackney, and Holborn.

#### EXTENSION OF THE NORFOLK AND NORWICH HOSPITAL

Sir Kingsley Wood, M.P., Parliamentary Secretary to the Ministry of Health, opened, on November 25th, the new out-patient department of the Norfolk and Norwich Hospital, which has been erected on the site of the old department. The main entrance is provided with a large glazed shelter allowing patients to be removed from an ambulance under cover. Out of the well lighted waiting hall open five consulting rooms, each with an attached examination room. Special arrangements are made for the examination and treatment of ear, nose, and throat cases, there is a complete operating block, and a recovery room for patients after minor operations. Accident cases will be treated in a special casualty room. On the first floor accommodation is provided for ophthalmic and dental out-patients, including perimeter, operating, dental, and dark rooms. Sir Kingsley Wood in his speech referred to the foundation of the Norfolk and Norwich Hospital 156 years ago, and said that the Government would do all they could to encourage voluntary hospitals. He did not think that an attitude of pessimism with regard to the health or physique of the nation was justified, in view of the increasing enlightenment of the people generally, the decrease in the mortality of infants and children, and the progress made in medical science.

## Scotland.

#### ROYAL INFIRMARY, EDINBURGH

The report presented to the ninth annual meeting of the League of Subscribers of the Royal Infirmary of Edinburgh by Mr George Mackay stated that the amount received from various groups of small subscribers was £21,420, a slight increase on the previous year. Edinburgh had subscribed £15,931 and the balance had been collected in country districts, especially in Fife, the Lothians, and the Border counties. Owing to trade depression, a much smaller number of subscriptions had been received in some districts, but this had been more than counterbalanced by the general rise in the number of subscribers. During the year 85 new groups of subscribers had been added, and the league now had a total of 1,418 groups. Since the commencement of the league in 1919 the total sum gathered for the Infirmary had reached approximately £159,000. The report in regard to the working of the

Infirmary showed that the number of patients in the wards during the year had been 17,843, as against 17,024 during the previous year. As regarded the occupations of those admitted to the hospital, or the occupations of those whose dependants were admitted, the greatest number were workers in mines and oil works (2,644), trades and crafts furnished 1,536 and general labourers 1,416, domestic servants 980, persons employed in offices 797, and shop employees 758, railway employees numbered 569, motor mechanics 445, building trades 311, and engineering works 339. The number of out-patients continued to increase, the past year's figure being 61,582. Unfortunately there continued to be an extensive list of persons waiting admission, which on November 1st had numbered 1,923 cases. Nothing except an extension of accommodation would relieve this difficulty, which, however, was common to other hospitals in the country. Contrasted with the previous year, almost every item of voluntary revenue showed an increase. The expenditure for the year had been not less than £140,000, an increase of fully £10,000 over the previous year. Referring to the cost of food, it was mentioned that 80,300 gallons of milk had been used, costing £5,300, while the meat and poultry required had cost £4,676. There had been an increasing tendency to substitute fruit as part of the diet.

#### THE MILK SUPPLY OF CITIES

At a recent meeting of the Glasgow University Society of Agricultural Science the question of the milk supply for cities was discussed. Principal W. G. R. Paterson presided. Mr Alexander Batchelor (Dundee) spoke in favour of pasteurization of milk, and said that he believed no outbreak of infectious disease had ever been traced to milk which had been pasteurized. This process saved life and prevented disease, for in the case of some epidemics the proper pasteurization of a suspicious supply had resulted in the disappearance of the epidemic. General scientific opinion now held that such milk was unimpaired in its nutritive qualities. Various authorities in America were quoted to the effect that pasteurization would make unsafe milk safe, and that municipalities should safeguard their milk supply by this means. It was now generally agreed that even the lowest grade of milk should be at least safe. He pointed out that in the city of Edinburgh in 1926 the consumption of the highest grades of milk was 348 gallons daily of certified milk, 253 gallons of Grade A tuberculin-tested milk, and 52 gallons of Grade A milk, but that the total of these amounted only to 2.75 per cent of the whole daily consumption of milk in Edinburgh, which was 24,000 gallons.

#### REPORTS OF ASYLUMS

##### Rosslynlee Asylum

The report by the medical superintendent, Dr J. H. C. Orr, on Rosslynlee Asylum of the Midlothian and Peebles District Board of Control for the period to May 15th, 1927, states that the number of patients on the register at the end of the year was 337, including 12 private patients and 16 service patients. The ages on admission varied from 5 to 85 years. Sixty-six per cent of the patients admitted were in a weak state of health, and in fully one-third of the cases hereditary predisposition to mental derangement could be traced. Of 43 patients admitted, 17 suffered from melancholia, 10 from mania, 7 from senile insanity, 5 from adolescent insanity, 2 from delusional insanity, and 1 each from idiocy and general paralysis of the insane. The congenital idiot was the child of a mentally defective mother. There were 33 deaths during the year, and in two of these cases the patients had been resident in the institution for forty-two years.

##### Inverness District Asylum

The annual report for Inverness District Asylum by Dr T. C. Mackenzie, medical superintendent, dealing with the year to May 15th, 1927, shows that on that day there were 723 persons on the roll, with an average number throughout the year of 711, the total number of cases treated was 865. The admissions had numbered 148, as compared with 162 in the previous year, and the discharges 74, as compared with 93. Of the patients admitted 32 had been previously

under asylum treatment and the rate of admission varied from 10 to 61 per cent. Sixty-one cases had suffered from melancholia, 28 from mania, 41 from dementia, of whom 20 were associated with senile decay, 4 had been cases of congenital mental deficiency and 3 of general paralysis. Dementia praecox accounted for 13 of the 61 cases returned as melancholia and for 9 of the 41 cases of mania. It thus appears that even one-fourth of all the admissions were for dementia praecox. It is pointed out that this disease does not mean early death, the patient's tendency to recover, so that cases of this type form one of the chief reasons for the periodical necessity of enlarging mental hospitals. With regard to causation, hereditary predisposition to insanity was found to exist in 65 of the 148 admissions, while senility was the assigned cause in 34 cases and alcoholism in 4. Out of the 63 deaths during the year, 9 were due to pulmonary phthisis and 23 to senile decay, the two causes therefore were responsible for 47 per cent of all the deaths. The report includes some valuable remarks upon the observations of the Royal Commission on Lunacy and Mental Disorder in which the relative supplies of lunatics in Scotland is compared with that in England is pointed out.

## Ireland.

### TRIBUTE TO THE LATE PROFESSOR OF ADRIAN STOKES.

At a meeting of the Section of Pathology at the Royal Academy of Medicine in Ireland held in Dublin at the Royal College of Physicians the President Professor T. T. O'Leary in the chair the following resolution was proposed and passed in silence, the present standing.

At this sad meeting of the Section of Pathology in the year 1917-18 the Section of Pathology is deeply affected by the death of Adrian Stokes, who took place in Africa on September 15th from yellow fever contracted in the course of his investigation into the cause of that disease. Although he had been for five years, Sir William Dunn professor of pathology at Guy's Hospital his career as a student in Trinity College as a student in the school of pathology and later as professor of bacteriology and preventive medicine in and in Flanders during the war years will be remembered by the Fellows of the Academy to which he made many contributions. Not a one was he chief of the most distinguished of the younger generation of our country members of the medical profession giving promise of a brilliant future. Of it is true but he was a great personal friend of many among the profession in Dublin. Professor Stokes in his all too short career led from literature on Irish medicine and well as the tradition of a family for many generations in the forefront of medical and surgical progress. The Secretary is instructed to convey to his brother Henry Stokes our condolences with the number of his family our own of the great to which we turn in general and pathology in particular has increased and our gratitude for the stimulating example of one whom it was an honour to have known.

### REPORT OF POOR LAW COMMISSION (NORTHERN IRELAND).

An important meeting of the Tyrone Division of the British Medical Association was held recently in the Tyrone County Hospital. Dr F. C. Thompson, D.L., chairman of the Division presided. The first business was the election of a chairman and other officers for the ensuing year. Dr T. Lyle, Newtown Stewart, was unanimously appointed chairman. Dr F. Bradley, vice-chairman. Dr W. P. Lynch, Orlogh, honorary secretary, and Dr Thompson representative of the Division on the Central Council. The next business on the agenda was the consideration of the medical relief system which consists in the examination of insured persons by doctors in general practice who may be in competition with their confreres. This has been objected to by the medical profession in Northern Ireland generally, and six months ago a deputation waited on the Minister of Labour and expressed their dissatisfaction. It was then determined that if dissatisfaction still continued the deputation should have the opportunity of again discussing the question with the Minister. Several of the members expressed their continued dislike of the system which was unfair to the medical profession and injurious to the interests of the poor. Finally it was determined to direct the attention of the Branch Council of the Association in Belfast to the question and to request a further

inter-visit with the Labour Minister. A circular from the Medical Secretary of the British Medical Association was read urging the necessity of local medical health lectures to arouse the interest of the public in matters so closely concerning their own health and interest. The object was approved but it was considered that there would be great difficulty in organizing such lectures in the absence of public interest. At the request of the Executive Committee of the Division Dr L. Kidd, Linnishillen, was present and explained at length the proposals contained in the Poor Law Commission report. The Commission was composed of thirty-seven persons, eight of whom were doctors. It spent three and a half years in taking evidence and, as far as the medical profession and public were concerned, produced almost word for word the recommendations of the Viceregal Commission which were pigeon-holed twenty-one years ago. The same fate was likely to attend the present report since there seemed little enthusiasm for it on the part either of the general public or of the Government. Its chief friends were undoubtedly to be found amongst the doctors and even they though they had made many most valuable suggestions seemed lukewarm. The report recommended the abolition of boards of guardian chiefly because their duties were divided in matters of public health with the district councils. The county council was to be the chief administrative authority aided by the dispensary and public health committees. County houses were to replace the present workhouses and fever hospitals were to be centralized where possible. District hospitals were to be retained and improved. The county hospitals would be enlarged and fitted with necessary modern surgical and medical appliances and more closely associated with the district hospitals. Dispensary and public health committee would be formed and a medical officer of health appointed with assistants who would look after the sanitation of the schools and children. Sanatoriums should be enlarged and properly equipped. Small sanatoriums were unnecessarily expensive. Provision should also be made for the treatment of surgical tuberculosis at present it was very deficient and unsatisfactory. Dr Kidd strongly denounced the absence in the report of any mention of a Minister of Health without whom any attempt at health reform was impossible. If such an official were elected by a department of the Government and skilled doctors was considered essential in England and Scotland why not in Ireland. Unless the answer was in the affirmative in the six Counties the Government might whistle for effective health control. As a matter of fact there was no trained and experienced medical department at present in connexion with the Ulster Government. The question of medical benefits was closely argued and debated by the Commission. It was at first affirmed and then finally withdrawn. Undoubtedly there was considerable support for the idea in the Ulster counties. Dr Kidd finally suggested that this report should receive the closest attention of the medical profession and that its considerations should be of force underlain by the central body in Belfast. Dr Kidd also drew attention to the form of medical certificates now required by sick jurors. He pointed out that this certificate required for the judge's information the name of the disease and particulars of the origin and symptoms of the affection on account of which the juror was absent. The general opinion was that the requirements of this certificate were iniquitous and should be resisted. Attention was also drawn to the small fees now paid doctors a visit. Dr Abernethy stated he was offered 1s. for giving evidence before a magistrate in Omagh and others present gave examples of inadequate payments. Dr Kidd said that doctors had only themselves to blame for these examples of injustice and until the profession aroused itself the members might be prepared for further exactions. Dr Thompson in conveying the thanks of the meeting to Dr Kidd dwelt on the importance of the discussions, and impressed upon the members the necessity of adopting Dr Kidd's advice to show a greater concern in local affairs so as to be able to protect not only their own profession against injustice, but also the wider interests of those who relied upon them in everything relating to public health or the community.

## DIATHESIS AN APPRECIATION AND A PROTEST

SIR,—Whilst yielding to none in the sense of admiration for the brilliant contributions of Sir Archibald Garrod to abnormal metabolism, a word of warning is necessary with regard to the anthropological and statistical approach to diathesis. Anthropology is still "a lucid madness engaged in fabricating its own hallucinations."

The ancient theory of the "humours" has undergone many a subtle paraphrase in the hands of Sigurd, Kitchener, and others. The classification of Mills in terms of "hyposthenia," "sthenia," "hyposthenia," and "isthenia" had this advantage—it was based on direct radiological observation of a large number of human beings in relation to bodily habitus, and allowed a non-rigid grouping, which yielded in each group 5, 48.35, and 12 per cent respectively. Hurst goes much further and states that the hypertonic and atonic stomach are associated with differences in length and secretion. Are we to infer that this applies to the 5 per cent and 12 per cent of Mills, and that the two overwhelmingly intermediate groups are guaranteed against alimentary disease? Hurst stresses the non-pathological range of normal variation, but his followers do not. Moody has shown that enteroptosis, gastroptosis, and coloptosis are non-pathological, and that the powers of emptying the viscera are independent of their position.

Both Bräuna and Liebzelter, and Neuner and Feldweg, have recently illustrated the pitfalls of anthropological classification in an index of diathesis, and Bräuna gives a concise history of the various methods. Dravenport, in *Body Build and Its Inheritance*, concludes that slenderness of build is associated with tuberculosis, pneumonia, nervousness, and melancholia, fleshiness with diabetes, nephritis, arterio-sclerosis, and numerous diseases of the alimentary tract. Draper, in his study of the fashionable "constitutional medicine" based on less than 300 patients, suggests that there is a typical facies and a typical build for groups of patients suffering from particular diseases. The indiscriminate acceptance of these views lands clinical medicine in the realms of horoscopes and the like.

Jackson has recently published an excellent survey of 1,633 male university students from the point of view of stature, sitting height, weight, chest expansion, vital capacity, pulse rate, systolic blood pressure, and exercise tolerance. It is in apt display of the unimodal curve in relation to bodily habitus, there is no evidence of Mendelian factors is suggested by Dravenport, and there is but small correlation between body build and cardiovascular or respiratory functions. This is a matter of first magnitude in relation to diathesis.

The problem of diathesis can only be solved by studying large numbers. The Ministry of Health and the Board of Education, with twenty years of medical inspection of schools, have the necessary numbers for a comprehensive survey of the norm of physical efficiency, body build, and diathesis in large numbers of different age groups. This would be of prime importance to workers in many fields, for little of real importance has appeared in this country since the report of the Anthropometric Committee of the British Association in 1883—I am, etc.,

H. A. HARRIS,

(Institute of Anatomy and University  
College Hospital)

December 1st

## CATARACT AND ULTRA-VIOLET LIGHT

SIR—The letter of Dr Percy Hall in your issue of December 3rd (p. 1061) on cataract and ultra-violet light calls for comment. Mr Bishop Haiman suggests that this agent probably causes cataract while Dr Hall apparently uses it as a method of treating this condition. Such a question can most reasonably be answered by a direct appeal to experiment. I have produced cataract experimentally in animals by radiation, both with infra-red and

with ultra-violet rays, nor am I the only one who has done so. These results, and the literature of the subject, will be found in my paper on the pathological action of light upon the eye, published in the *Lancet* (1926, vol. 1, pp. 1137, 1188, 1250, and vol. 2, p. 16) where, incidentally, all the matters under controversy are dealt with in detail.

From the theoretical point of view this is merely what one would expect. Cataract is a coagulation of the proteins of the lens, and proteins are coagulated by ultra-violet radiation. The coagulation of proteins is an irreversible chemical change, to talk of this process being reversible (unless the whole of our ideas of the chemistry of proteins are to be revolutionized) is frankly illogical. From the clinical point of view, although ultra-violet light has a very definite and useful place in the treatment of diseases of the eye, my claim to "cure" cataract by radiation of any kind can only be ascribed to inaccurate observation, or to a failure to assess the complicated systemic influences which from time to time may alter the refractive properties of an unstable lens.

It would indeed be well if, in the hands of many, both medically qualified and otherwise, ultra-violet light were employed with more discrimination based on ascertainment of experimental data, and with less enthusiasm—I am, etc.,

W. S. DUFF-ELDER, D.Sc., Ph.D.,

London, W. 1, Dec. 3rd

M.D., F.R.C.S.

## TREATMENT OF PROSTATIC ENLARGEMENT

SIR—While great progress has been made in the general operative technique of suprapubic prostatectomy, since the late Sir Peter Freyer popularized this method in England, the mortality rate has not diminished *pari passu*. The various methods of testing the renal efficiency previous to operation should eliminate cases in which the kidney function is seriously impaired and the chances of recovery thereby correspondingly diminished. Yet, nevertheless, the mortality still remains serious, and the general practitioner has some excuse for pessimism when he hands over his patient to the surgeon, the death rate of 40 per cent which Mr Hey Groves calculated from the available statistics of large hospitals in Great Britain is alarming. The test of progress should be the mortality rate. I have always looked upon suprapubic prostatectomy as a special operation requiring in its performance a particular knack or gift which is only acquired by, or bestowed upon, individual surgeons, who eventually specialize in this particular branch of surgery, so long as it is claimed that this operation is part of general surgery the mortality rate will remain where it is. Freyer limited his practice almost entirely to this organ, and his record is still enviable, but those surgeons who specialize to-day in this particular branch will be found to be doing even better. Freyer's mannerisms in the operating theatre were thought by many unduly dramatic, but he had one great characteristic which always impressed me, and that was his attention to the time factor in all his operations upon elderly men, he kept his eye on the clock as well as on his mortality rate.

Elderly men, whether their kidney functions are ideal or otherwise, will not stand prolonged operations, and, however perfect the prostatic cavity may be after operation, the sooner the operation is over and the patient is back in bed the better are the chances of recovery. I have seriously considered this time factor in all cases, and, though I have adopted the open method with its more perfect technique, there can be no doubt that the operation is thereby prolonged. To obviate this disadvantage I have recently used a low surgical diathermy current to treat the haemorrhage after trimming the neck of the bladder, the current used being merely strong enough to coagulate the blood. This procedure is much more expeditious than ligaturing or stitching the neck of the bladder. It has only been tried in three instances so far, but the results were very satisfactory in that there was no primary or secondary haemorrhage in any of the cases. It is too early to express any definite opinion as to the future of surgical diathermy in prostatectomy, but the benefit so far obtained is sufficiently good to indicate its possibilities, and any method which will shorten the duration of the operation will be of value.

I disagree with Sir Cuthbert Wallace (JOURNAL, November 19th, p. 907) as regards his after-treatment. I consider it essential to irrigate the bladder thoroughly, but gently, twice daily, since this is the only way the prostatic cavity can be maintained clean in the suprapubic operation, unless a catheter is kept in, which is disliked by the majority of patients. I irrigate by Junc's method, though the method is soon as the patient can tolerate it. A clean prostatic cavity after operation lessens the chance of orchitis and epididymitis later.

With regard to sexual function after the suprapubic operation I would refer Sir Cuthbert Wallace to Mr B J Ward's article "The immediate and remote results in 109 cases of suprapubic prostatectomy by Junc's method," in the Birmingham Medical Review of March 1908, where it is claimed that in a certain number of cases this function is retained.

Sir Cuthbert's interesting lecture and figures afford clear evidence of the necessity for establishing genito urinary departments in all our large general hospital and for encouraging specialization in this important branch of surgery—I am, etc.,

LONDON W1 Nov 2, 1927

T CAREY EVANS

### THE TEMPERATURE IN TUBERCULOSIS

SIR—My attention has been called to Dr Varrier-Jones's little book on *The Significance of Temperature Variations in Tuberculous Disease*, reviewed in your issue of November 19th (p. 9-10). I do not find it easy to understand why a complicated and expensive mechanism should be suggested for recording the temperature variations in tuberculosis when a clinical thermometer supplies all the information required without any serious inconvenience to the patient. In tuberculosis it is of the highest importance to obtain a continuous record of the variations of temperature, not merely for twenty-four hours but rather for weeks and months and years, day by day, so that one can watch the activity of the disease closely and carefully in its wearisome progress during the whole period of treatment.

The cumbersome methods advocated by Dr Varrier-Jones could not be applied to a dozen cases even for a few months, and the information would not be as valuable as the information I have been collecting for thirty-five years with the simple clinical thermometer. But the clinical thermometer must be used in the right way.

I am surprised also that Dr Varrier-Jones should dogmatize upon the nature of the tuberculin reaction without having made as far as the letterpress shows any attempt at observations. Such accuracy demands that for diagnostic purposes the exact amount and variety of the tuberculin used should be definitely stated.

There are numerous varieties of tuberculin which I have used in literally thousands of cases of tuberculosis, and I have kept temperatures in all my cases not only for years but for decades. Long ago I recognized and taught that great care was needed in the measurement or graduation of the dose, and that anyone experimenting with tuberculin must prepare his own doses. Then only does he know what the dose is when it was prepared in the form of tuberculin and even when manufactured it. Many tuberculins on the market are untrustworthy, and chemists are not the best persons for measuring the doses.

Let me cite one illustration. The dose used by Dr Varrier-Jones in human beings was T.R. (0.0001 mg.) [i.e.] pag. 77 "T.P." a fluid preparation and cannot be measured in milligrams. What is the dose weight? On page 63 we read "the effect of a dose of tuberculin (0.001 mg. of Koch's bacillus emulsion) [i.e.] This small amount can be measured only by fluid measure. On page 7 we read "After the injection of 0.001 mg. tuberculin a curve was obtained (Fig. 29) [i.e.] and on referring to Fig. 29 we find the dose recorded is 0.0001. On pag. 77 we read "resulting from the following in of a much comparatively large dose of tuberculin (Fig. 29). Neither in the letterpress nor on the chart is the amount of the dose stated. Worse still on pag. 110 we learn that a dose of 0.0001 mg. of B.E. was given and on the next page that there being no plateau formation tuberculosis was diagnosed.

Such records can only bring tuberculin as a diagnostic agent into discredit.

I venture to say that such a use of tuberculin for diagnostic purposes is ridiculous, and owe it to the Tuberculin Dispensary would prove this. Struggle to win no

controls by simultaneous readings of the ordinary thermometer are reported, and no observations of the pulse and weight, not any mention of trick reactions or intravenous reactions. These isolated observations by Dr Varrier-Jones cannot help in the diagnosis of early tuberculosis. Why has he not tried the methods proved to be trustworthy by hosts of authorities or at least controlled his own procedure by observations according to established methods?

On the other hand in describing experiments upon bovines which were being tested with tuberculin Dr Varrier-Jones states, page 86 line 4 "after a twenty-four-hour record had been obtained 6 c.c. [sic] of tuberculin was injected subcutaneously." Why is tuberculin, used for bovines properly measured in cubic centimetres, and that used for human beings measured in milligrams? Further on whose advice was 6 c.c. injected into a calf for test purposes? Moreover surely the term or tuberculin used should be stated. In such a system or dosage were practised tuberculin had better be left severely alone.

Dr Varrier-Jones advocates the rectal temperature, and that only is reliable. Thirty-five years' constant use of mouth temperatures taken by patients with special directions every two or four hours leaves very little to be desired in judging the differences of temperature upon which without or with tuberculin success in diagnosis, prognosis and treatment essentially depends. I can furnish studies or evidence of the truth of this apparently bold statement and I believe that anyone who has worked with me at the Tuberculin Dispensary for a sufficient length of time will support me on this crucial question—I am, etc.

W. CARL WILKINSON, M.D.  
Director, Tuberculin Dispensary  
2 Fitzroy Street W1

Nov 26/27

### RISKS OF LIGHT THERAPY

SIR—The lack of sunshine during our winter months has led to an increasing demand for irradiation of the skin with artificial sources of ultra violet rays. It is necessary to realize that many of the lamps employed for this purpose emit ultra violet rays which differ in quality and quantity from the sun's rays. Professor Leonard Hill has shown that the biological action of the sun's rays are due to the ultra violet rays 3360-3600 Å. The long flame arc and the quartz mercury vapour lamp have their maximum biological action from ultra violet rays shorter than 2970 Å, which are absent in the sun's spectrum. The result of my experiments have led me to adopt a specialized technique of treatment which I have called "short ray therapy" in contrast to the "Finsen technique" which is adopted in the Copenhagen Light Institute. Further research may well determine the relative value of each form of therapy and will decide when an Finsen or ultra violet therapy is indicated. But at the present moment it is imperative to realize that when short ray lamps are employed emitting ultra violet rays shorter than 2970 Å, the principle of short ray therapy should be adopted.

The danger of over exposure has resulted from the confusion of principles and the misapplication of technique. In this country the normal white skin is very sensitive to short ultra violet rays from 2970-2500 Å, and the reactions of the skin resemble those of the irritant and endothelial reaction. From this point of view I would suggest that short ray therapy should be controlled and entrusted to the chemist who is fully trained to understand the correct application of light rays. For home use and general treatment lamps emitting ultra violet rays 4000-3600 Å, which are similar to the effect of the ultra violet rays of the sun should only be employed. This can be obtained by the use of carbon arc lamps containing a glass screen, quartz mercury vapour lamps with frosted vitreous arc or a mercury vapour lamp made of vitreous. The abuse of light therapy by unskilled and badly trained workers and campaigner's violent propaganda have led to a considerable number of cases of skin cancer and other conditions. I am, etc.

W. L. E. EMBROW

ULTRA-VIOLET RADIATION AND VARICOSE  
ULCERS

SIR,—I entirely agree with Dr Weimien regarding the value of ultra-violet irradiation for varicose ulcers. Even with small recent ulcers it is the quickest way to heal these, to tone up the flabby tissues, to increase nutrition, and thus to prevent recurrence. In large chronic ulcers that have resisted all measures it is still the best way. Technique here, however, is all important, and results will never be achieved if the treatment is left to nurses and missesses, it needs constant medical supervision.

Fulmo is due, I think, to a want of discrimination between the effects of different sources of light. I have had uniformly good results in the light department at St Mary's Hospital. As these ulcers are all septic the first thing is to use the bactericidal power of light on the ulcer itself by a few short, sharp, stimulating irradiations with a source of light rich in the shortest ultra-violet rays—a fairly new mercury vapour lamp at a distance of 40 cm for three minutes, or a Kromayer at 20 cm for two minutes. This causes an outpouring of serum, which cleanses the wound and removes fragments of dead tissue. Two or three applications are enough completely to alter the appearance of the ulcer. To continue strong radiation after this is wrong, as the delicate new granulation tissue is seriously damaged by powerful actinic rays. We now need the germicidal and keratotic power of light for the ulcer, so use of a longer wave-length is indicated for this and to increase the nutrition of the surrounding tissues. If another source of light is available, such as an iron or a carbon arc with metal core, containing the longer ultra-violet and the more penetrating yellow, blue, and infra-red rays, ten to fifteen minutes' treatment can be given with these, at a distance of about 60 cm. If not, the same mercury vapour lamp can be used in combination with the solar or other source of infra-red rays at a distance of 100 cm. Under this treatment chronic serious infiltration of the surrounding parts disappears, also the pain and nutrition. The ulcer loses its torpid character, and vigorous granulations replace the dirty sloughing base. The indurated edges flatten, and epithelization takes place more quickly than by any other method.

The third stage is treatment of the whole leg until good pigmentation is achieved. Excessive stimulation must be avoided if there is any sign of thrombo-phlebitis. Later on the dress can be used until hyperemia appears as a faint red-bronze tint showing through the pigment. It is, of course, essential to support the tissues by an elastic bandage from too to knee, over the dry gauze dressing and soft bandage. Parathyroid in small doses is helpful.

The same technique can be adopted for the deep perforating ulcers of tibiae, on the sole or toes.—I am, etc.,  
JUSTINA WILSON, M R C P Ed,  
D M R C Camb

London W 1 Nov 15th

SIR,—Dr Weimien (November 12th, p 900) draws attention to the wide divergence of opinion among dermatologists as to the value of actinotherapy for varicose ulcers. Evidence in favour from another country is useful, so I will mention how Dr Suidman of the Institut d'Actinologie, Paris, demonstrated to me a case of varicose ulcer of twenty years' duration, in the final stages of healing with ultra-violet therapy. That case alone fully justified an optimistic prognosis even in apparently hopeless cases of chronic varicose ulceration.

Besides its general tonic effect, now generally accepted, the local application of ultra-violet light stimulates diapedesis, as can be demonstrated easily by its dissipation of the swelling, pain, and discoloration of a burn, therefore ultra-violet therapy appears to be the treatment of choice to apply on and around the ulcerated varicose ulcer, as it will antagonize the condition of venous stasis.

That it will stimulate the growth of epithelium is proved by its use successfully in the treatment of a burn with molten lead containing arsenic—a burn wide all the more severe because the molten metal ran inside the upper of a boot and was thus some time in contact with the skin, the destruction of tissue was more extensive in area and in depth than in a varicose condition, yet healing took place without grafting.

In the treatment of varicose ulcer with ultra-violet light the patient will be grateful for the relief of pain and irritation, which is a feature of the process of healing under these rays, but more remarkable still, in my opinion, than its success in the treatment of superficial varicose ulcers or burns is the results obtained in gastro-intestinal conditions which present the classical signs and symptoms of chronic ulceration, with eight to twelve treatments the patients lose pain, discard their milk or light diet, and eat "what is on the table"—that is, pork, oven pie, blattens, tinned salmon, and pickled onions—with relish and benefit, as is evidenced by improved colour and increase in weight.

Scientists tell us there is little penetration by the ultra-violet rays, and I attempt no explanation here of how this beneficial action takes place, but to me varicose ulcers present an easy problem compared with those other ulcerative conditions mentioned—I am, etc.,

Newcastle on Tyne, Nov 13th

CHRISTINA BARROWMAN

SIR,—In a letter in your issue of November 12th (p 900) commenting on the discussion on ultra-violet light treatment of skin conditions at the Annual Meeting of the British Medical Association in Edinburgh, and the divergence of opinion among dermatologists as to its value, the writer quotes, amongst others

*Prurigo (Adults)*—Dr Gardiner Aggravated Dr W J O'Donovan Improved

As one who was present at the meeting in Edinburgh, the question which at once presented itself was, to what form of prurigo did those who took part in the discussion refer when they spoke of "prurigo (adults)"? Discrepancies in results are readily explicable on the assumption that different types of "prurigo" in adults had been treated, apart from my consideration of the method employed.

The importance of a standard technique in comparing results is recognized, but at the same time when large numbers of patients are treated by an adopted "standard technique" it is a matter of common observation that there is marked variability in the individual response to ultra-violet irradiation. The true value of actinotherapy will only be assessed when numerous, detailed clinical records are available, and when every other contributory factor has been carefully considered.—I am, etc.,

Liverpool, Nov 22nd.

ELIZABETH HUNT, M D

## BRILL'S DISEASE

SIR,—I am sorry to see the term "Brill's disease" used in the note (December 3rd, p 1044) respecting the epidemic fever which has been prevalent in Muscilles and its neighbourhood. I am sorry for two reasons. The first is that "Brill's disease" is typhus fever and nothing else. The second is that the Muscilles disease has, apparently, not been quite certainly shown to be typhus. Judging by the very brief account given in the note, the disease seems to me to be different from typhus.

Brill's first account of the disease which has been called after him was based on his experience of a number of sporadic cases admitted to a hospital in New York over a series of years. Brill admitted that so far as the symptoms were concerned the disease differed in no way from typhus fever as described by British writers. But he concluded that his disease was not typhus, because (1) it was sporadic and apparently not infectious, and (2) it was not fatal—none of his patients had died. Subsequently, however, instances presented themselves in New York in which more than one case occurred at the same time in the same house, and there were fatal cases. Further, the bacteriologists brought forward evidence that from their point of view Brill's disease was typhus.

After the disappearance from London of epidemics of typhus the disease persisted for many years sporadically. So far as I know, no one ever made the suggestion that the sporadic disease was not typhus. I have had personal experience of typhus as it occurred sporadically in London for over thirty years, and epidemically in Poland in the

autumn of 1919, and I have no hesitation whatever in saying that the clinical symptoms were the same in each set of cases. Similar attempts to differentiate a mild form of typhus as a new disease have recently been made in various parts of the world (India, Australia, the Malay peninsula) and another reason has been urged for the distinction—namely, that the incubation of the believed-to-be-new disease is not conveyed by lice. But if the mode of spread is to be used as a criterion of distinction then we had better call milk-borne scurlet fever "Powers disease" and so on. Brill's disease" and "tropical typhus" are typhus fever pure and simple and it will lead only to confusion to continue the use of the newly applied names.

Permit me a word or two respecting the value of the Weil-Felix reaction in the diagnosis of typhus. As I have stated above there appears to be some doubt whether the Marcellus disease is or is not typhus. But I should not be surprised to learn that even if the disease were shown to be indistinguishable from typhus clinically there had been a negative Weil-Felix reaction in every case provided that only two or three strains of *B. proteus* X had been employed. According to a very instructive paper by Fletcher and Lesslar (*Bull Inst Med Res Fed Malay States* 1926, No 1) several strains of the bacillus must be used before the reaction can be stated to be positive or negative. They were able to divide nine different strains into two main groups, of which the one was distinguishable from the other by differences in certain fermentation and agglutination reactions—I am etc.,

Hemingford Abbots Hunt Dec 11

E W GOODALL

#### WATER SUPPLY AND IODINE IN RELATION TO GOITRE

SIR,—During the last seven years I have had considerable experience of three rural or semi-rural medical practices in places so far apart as Lincolnshire, Somerset and Sussex and in each I have been particularly struck by the prevalence of cases of disordered thyroid metabolism more especially of the type that is indicated by parenchymatous enlargement of the thyroid gland in young girls at and for a few years following the age of puberty indeed this has been one of the commonest non epidemic conditions with regard to which my advice has been sought.

Cystic and adenomatous enlargements of the thyroid have also been common amongst older people. Cases of exophthalmic goitre, of carcinoma of the thyroid and of myxoedema have been relatively rare. A few cases of cretinism have been found.

Just as in the deficiency diseases like scurvy and beriberi there are early and intermediate stages between complete freedom and the fully developed disease which are often exceedingly difficult to diagnose so in disorders of the thyroid, whether showing hypertrophy or atrophy of the gland, there must be a variety of intermediate conditions leading to physical and mental weaknesses which may escape the observation of the most careful diagnostician. For example, it is not improbable that the slow wit of the agricultural labourer may be due more to the condition of his thyroid than to his somewhat dull surroundings.

Without having any definite figures on which to rely I should say that goitre and thyroid atrophy are more common in rural than in urban areas whilst it is I believe a fact that they are much more prevalent in some rural districts than in others. In the only other district with which I am well acquainted—the county of Antrim—parenchymatous goitre at least is uncommon but there are doubtless similar free areas in England and in Scotland.

Various theories have been advanced to account for the occurrence of simple goitre: those that hold the field at the present time being (a) deficient iodine content in food or in drink (b) malnutrition on the part of the thyroid for some unspecified reason, to make use of the term though present in the food or drink in normal quantity (c) bacterial infection (d) vitamin deficiency. With regard to (a) it has been suggested that distance from the sea is the prime factor in determining the amount of iodine present in vegetables or in water, but none of my practices in any

of the above countries were at an considerable distance from the sea whereas in Central India a far longer distance, in my experience is common.

It is true as I imagine it is that goitre is more prevalent in certain rural areas than in towns within the same area, it ought to be possible to discover in what conditions differ in the rural as compared with the urban area and the first thing to which one's mind naturally turns is the water supply. Towns are supplied usually (in this country at least) with a pure and filtered water, kept under chemical and bacteriological observation. In rural areas water is got from the nearest well which is often open to suspicion even to press contamination and receives little expert attention. The food supply of these urban and rural areas must necessarily be identical so that the cases of iodine and vitamin content are concerned.

Similarly with regard to two rural areas in one of which goitre is common in the other about it ought to be possible to discover how conditions differ in the two areas. For the present and until light on the subject is forthcoming, my advice to all householders with whom I have to deal is: boil your drinking water—I am etc.

T S ROSS

Lieut-Colonel R.M.S. (ret.)

Newick Sussex Nov 17th

#### CHRONIC APPENDICITIS

SIR—I was disappointed that there was no mention of the value of X-rays in the diagnosis of chronic appendicitis when this subject was discussed at the Annual Meeting of the British Medical Association at Edinburgh. Admittedly it is difficult even when the appendix is visible—which is not often—but when this organ does fill several points can he made out.

- 1 There may be fixed lumps and strictures
- 2 Tenderness localized to the appendix and conclusive evidence of disease
- 3 Abrupt interruption of the column of barium is indicative of prism due to ulceration
- 4 Interference with the muscular tone and contractility shown by delayed emptying up to several days and the presence of large concretions or the failure of movement after several days

Dr E I Spence has contributed several examples to the literature. Surely in a disease whose symptoms are so vague as chronic appendicitis we must seize on every possible means of diagnosis and radiology can play a useful part—I am etc.

Harrow Aug 16th

#### THE PREVENTION OF MATERNAL MORTALITY

SIR—In the *BRITISH MEDICAL JOURNAL* of November 5th (p. 833) Sir George Newman speaks of three needs. First, the pregnant woman should consult her doctor at the earliest opportunity. Second, maternity homes. Third, skilled and competent assistance at childbirth.

This is the whole subject in a nutshell. He then proceeds to crack the nut and under the third heading he speaks of nothing but the skilled midwife. Surely skilled assistance at childbirth needs more than a midwife's allowance to do. Look on and allow nature to take its course. The medical man is the one who should have charge of the case, whether a midwife employed or not. I thoroughly endorse the letter of Dr A Campbell Sars on page 848 of the same issue.

Coming to the practical side of the question I consider that prevention is better than cure and it deals with such as I give below were carried out we should hear less of maternal mortality.

I Strict asepsis as regards patient, doctor, nurse and surroundings. At present the patient is never prepared to a surgical degree and as the anaesthetic is so close to the neck of operation it should have special attention. An anaesthetic should be a matter of routine and the patient should be prepared with a germicide such as a germicide iodine compound. This is the proper work of the midwife. Incidentally I

(1) *Bull. Med. Soc.* pp. 1-2 (2) *Lancet* 1923 vol. 1 p. 71  
(3) *Lancet* Dec 10, 1927 p. 1117 (4) *Lancet* Feb. 12, 1927 p. 1117

consider all pregnant women should be taught to wash these parts duly all through the carrying.

II Next in importance is the avoidance of real delay. Recent teaching tends to leaving the case to nature, which is all very well so long as nature is running a normal course, which is very seldom, under present circumstances. The position of the child is not everything. We have to consider the strength of the patient in body and mind. Stress of circumstances often causes irritability, impatience, and apprehension, the effect of the pains being utterly spoilt. And there is also the woman who means to be helped, whether you like it or not.

III In the present day too many doctors fail to study the different phases set before them, and have too few methods thought out of how to help, this is partly the result of present day teaching. What is wanted is the early diagnosis of these causes of delay. Such is

#### A rigid cervix

Slight divergence of the uterus from its proper axis

Premature rupture of membranes (a small Champetier de Ribes bag would alter the whole case in half an hour)

Non-rupture of membranes with little or no water behind the membrane tight on the head early rupture of these would expedite matters

Oedema of anterior lip of cervix not reduced

Most occipito-posterior positions would be better for version. Rotating the head is easier on paper than in reality. The use of forceps in this position is usually contraindicated.

Long-standing pendulous abdomen occasionally allows of turning, but, if extreme, calls for Caesarian section as replacement is more than likely to injure the bowel with fatal results.

A primipara at 38 to 40 years if there is much rigidity of the soft parts with narrowing of the vaginal canal, ought to be offered Caesarian section, so that the most unpleasant and unavoidable complications, such as rectocele, cystocele and vesico-vaginal and recto-vaginal fistula may be eliminated.

IV In forceps delivery the instruments should be removed as soon as the perineum is on the stretch, and delivery completed by the aid of the thumb in the ischio-rectal fossa, pressing forward. Axis traction forceps should be the rule. When the head is born it is injurious to the infant to wait for a pain, gentle traction on the head expedites delivery without any risk to the mother if a hand is kept on the fundus. The placenta should be expressed in due course during an interval of the pains.

These are a few of the aids to a woman which a medical man should always be on the look out for, to offer as necessity arises.

I would propose that the local medical specialist appointed by the Ministry of Health should be available to be called by any medical man in trouble, in the same way as any midwife is allowed to call in a medical man to her aid. The fee for such help should be paid by the local health authorities.—I am, etc.,

Wallington, Surrey, Nov. 10th

A. Z. C. CRESSY

#### A MISHAP WITH RADIANT HEAT

SIR,—The following unpleasant personal experience may be of interest, especially in view of the number of unqualified persons who are at present exploiting the little understood effects of ultra-violet rays.

On September 30th, in order to relieve some lumbar pain, which had resulted from a too vigorous use of a lawn-mower two days before, I was persuaded to try a "radiant heat" lamp. The lamp used was a 32 candle-power carbon filament lamp, British made, and stamped "Pope 10 amps for 230 volt current." Before using the lamp I had a hot bath with a handful of soda in it, which relieved the pain considerably. After rubbing a little ointment over the seat of the pain, which was chiefly around the left posterior superior iliac spine, the lamp was applied for twenty minutes at a distance of about 12 inches.

During the last five minutes of the twenty I felt some itching in the left leg, but half an hour later this itching had developed into the most intense, agonizing pain it has ever been my misfortune to suffer. During the hour that the pain was most intense I was bathed in cold sweat, my pulse became very rapid and could scarcely be felt, and I was on the verge of complete syncope. I certainly felt, and I believe looked, desperately ill. After about an hour the pain lessened, and with the aid of 1/4 grain morphine became bearable. But the whole limb felt num-

and useless, with the sensation of gross "pins and needles," which might perhaps be better described as "nails and tin-tacks."

Next day, when I first attempted to stand, my left leg gave way and dropped me on my knees. For some days walking produced intense fatigue in the extensor muscles of my left thigh, and I could not go up stairs except by keeping my right leg always in front.

This weakness has gradually got less, but still, nearly two months later, has not entirely gone. There still remains also loss of sensation, both tactile and to heat and cold, in a considerable area over the middle third of the left shin. I also feel undue fatigue in the left thigh muscles after a short walk or on going up steps.

I should be glad to know if a similar result has been noticed after using one of these lamps for the relief of pain.—I am, etc.,

Winton, Nov. 22nd

E. N. NISON

#### UNDERFEEDING IN EARLY INFANCY

SIR,—In your issue of November 26th (p. 997) is a note on a paper in the current number of the *Archives of Disease in Childhood* on "Underfeeding in early infancy." The authors claimed that the chief cause of gastric symptoms and failure to gain weight in infants under six months attending out-patient departments is that they are receiving an insufficient quantity of food. On these findings they put forward the plea for a revision of the feeding instructions on the tins of dried milks and other preparations.

There can be no doubt that the observers are correct in their deductions as to the cause of failure to gain weight amongst infants attending out-patient departments at children's hospitals, but to argue that all feeding directions are fallacious and to advocate feeding by weight and not age is a dangerous tenet that calls for careful thought and investigation.

Fifteen years' experience of children in out-patient departments has taught me that one seldom sees the normal, by that I mean the chief causes of malnutrition there seen are usually due to some extrinsic factor, either constitutional or infective—in fact, the cause lies in the reason of the infants' attendance at the hospital.

To be dogmatic about any dietetic factor as a result of hospital statistics is to court disaster. Especially is this true since the various centres, municipal and others, have added their valuable assistance in safeguarding the health of the infants. Rather is it to these centres, with their keen and efficient medical officers, that we should look for statistics with regard to, not only normality in infant feeding, but also the more simple diseases of nutrition.

Many of your readers may, on the strength of the article, be inclined to adjust, more or less empirically, the feeding directions on the tins of the various infant foods, with the result that they will risk overfeeding, which is a greater menace than underfeeding. My own experience is that these directions are in the main correct, and this, I think, will be borne out by medical officers at centres. Departures from the normal must be met as the clinical needs demand, but to alter the average for the sake of the few is a dangerous doctrine.—I am, etc.,

LEO MINDEL, M.D., M.R.C.P.

London, W. 1, Nov. 30th

#### CONVULSIONS DURING GENERAL AND LOCAL ANAESTHESIA

SIR,—From the experimental work detailed in *The Nature of Disease*, volume II, it would appear that anæsthetic substances act by subjecting the protein particles of the plasma to sudden dehydration and then to an equally sudden hydration. In the first process the protein particles go into solution and in the second process they migrate in size, lose their Brownian movements and tend to become precipitated in the pericapillary lymphatics and capillaries of the brain. It is to the protein particles becoming arrested in the cerebral vessels that the loss of consciousness is due. Should the hydration persist, or increase to a point where the surrounding nerve cells are damaged, the convulsions, coma, and death are liable to occur. The drug

action of dehydration and hydration is due to all anesthetic substances having negatively charged active groups and a positively charged vehicle. It is to the positively charged vehicle that excessive hydration of the toxic symptoms are due. It thus comes to pass that there is no fundamental difference between the convulsions occurring during anaesthesia and the convulsions caused by such drugs as insulin, eudazal, histamine etc. and to the convulsions that are met with in clinical conditions such as shock, eclampsia, status epilepticus, tetanus, etc. Status epilepticus is not a disease nor a condition due to an enlarged or persistent thymus. The thymus persists because the patient is intoxicated (chronic intestinal intoxication) and being intoxicated the protein particles are already hydrated before the anaesthetic which so intensifies the hydration is to cause death is used. As the toxic symptoms caused by anaesthetics are due to the natural action of producing hydration, the actual state in which the patient's protein particles happen to be before the anaesthetic is administered must play a greater part in the production of toxic symptoms than either the choice of anaesthetic used or whether it contains impurities or not. In considering impurities as the primary cause observers have missed the hyvistic in circling for the pins. As hydration can be prevented by subjecting the protein particles to conduction, and overcome when in being by causing them to become dispersed toxic symptoms can be avoided by the previous administration of such drugs as Sup 463 and parathionone and overcome by injecting glucose intravenously and oxygen subcutaneously—I am, etc.,

J E R McDONOUGH

### CONTRIBUTORY SCHEMES HOSPITAL CLUB PRACTICE

SIR—In your issue for November 12th last you were good enough to allow me to refer to certain considerations you had elaborated in your issue of October 22nd (p. 751) with regard to these numerous clubs.

Since then I have completed a restricted inquiry made with the assistance of Division secretaries and the honorary secretaries of visiting staffs of hospitals in various directions with regard to thirty-five clubs selected at random. Reports from thirty have been received. All, one feels sure, must appreciate and feel grateful to those who have assisted in this inquiry giving a return of over 90 per cent a result which has made headquarters envious. Possibly the result may interest many of your readers who are now considering this problem of hospital provision. (In cases where the total of figures does not make 30 it is because no reply was given to question asked.)

(a) Seventeen of these clubs are conducted by hospital 13 by independent bodies.

(b) One club (only) pays anything to the visiting staff.

(c) No club makes any arrangements for consultant or special services to be given either at the homes of the members or at the houses of these practitioners (whether members of the visiting staff or not). All members are attracted to the hospital.

(d) Nine visiting staff object to being paid for treatment given at a hospital 3 desire it 5 are divided in opinion 3 have not as yet considered it.

(e) Nine visiting staffs approve payment under (c) above one object, one is divided in opinion 6 have not as yet considered it.

(f) In 17 areas there are practitioners (consultant and special) available who are not on the hospital staff and who are of the British Medical Association standard of competency.

(g) In 13 areas treatment is provided for at the hospital which in the opinion of the local profession after considering the best interests of the patients could be equally well given at the patients' homes or the houses of the consultant and specialist (that is by the visiting staff and others in their private capacity). In 6 areas no such treatment is provided for at hospital.

(h) In 8 areas the surrounding cottage hospital are involved in the club in 6 of which the staffs are debarred consequently from accepting fees.

(i) In 12 areas there are sufficient funds in the club to assist convalescent home-nursing a vacation dental treatment and treatment of school children.

(j) The premiums for insurance in the club range from 2s a week to 21s a year collected by money boxes and visitors, or private houses and on the premises of shop and farm.

In our medical opinion with regard to the clubs, stated quite shortly, is as follows in thirteen areas.

(1) We are being exploited. (2) Considerable feeling against it. (3) A gigantic cheap club staff being elected every five years without opposition to board. (4) Consultants anxious all the time to have it. (5) Local profession against it. (6) Great abuse. (7) There is a strong feeling against the scheme. (8) They are we pay. I have also many complaints from general practitioners that the contributory scheme is hitting them. (9) Suspicion that the hospital is made into an insurance dispensary. (10) Protection too apathetic for words interests of local practitioners seriously affected. (11) Consulting work much diminished private operations much diminished shortage of beds prevents much more widespread inroads into both consulting and general practice. (12) Considerable local professional feeling against the scheme especially amongst the junior staff who are being deprived of a large amount of fees chiefly for minor operations and consultations. (13) The medical profession strongly averse from the scheme.

The public (lay) press is of opinion as recently expressed, that—

(1) The improved financial position of voluntary hospitals is due to contributory schemes. (2) Working men prefer dependence to charity. (3) They enjoy the status of independent persons who have insured themselves against emergencies and are under obligation to nobody. (Times November 29th 1927)

The deductions from the reports would seem to be

(1) That the premiums of insurance paid are totally inadequate to pay for the benefit contracted for by the club and that as a consequence charitable funds are used to make up the deficit in accommodation and maintenance charge the question of treatment being paid for is not thought of.

(2) Income limit is largely nonexistent.

(3) The very nature of insurance has created an increased demand for treatment and consequently the larger the membership of the club the larger the debt to be met by charity. In London the club has 400,000 members with 83,000 attendances as out-patient.

(4) The voluntary hospitals concerned have ceased largely to be charitable in nature for the poor having become an accessory of insurance club.

(5) Consequently it is a question of some interest whether these voluntary hospitals can claim any longer to be a body established to charitable purposes only. (Elizabeth C 4) and consequently can avoid being taxed and rated.

(6) These hospitals contract to provide many consultant and specialist services which—allowing for the best interests of the members of the club—could be given equally well and certainly more expensively at the homes of the members or the houses of the practitioners.

(7) Consequently the hospitals subsidized by charity, are under-elling private practitioners who are not on the visiting staff and who depend on their private practice for experience and remuneration.

(8) The boards of management—in many cases formed of a majority of the club officials—are the masters of the visiting staff.

(9) The visiting staffs in a few cases and the senior members (only) in the larger number do not appreciate (6) and (7) above or they would hardly continue indifferent.

(10) All the objections the profession had in 1903 to the dominion clubs conducted by friendly societies seem to be present in these hospital clubs.

Is not the whole position becoming derogatory to the dignity of medicine and can the visiting staffs much longer resist content to be on the position of errand boys into which they are being manoeuvred? As a suggested line for action which is in accordance with the hope of the British Medical Association would the visiting staff in cordial co-operation with the local Division and supported by its disciplinary powers (1) refuse to give any treatment at a hospital (whether for a club or for a private patient) a hospital (whether for a club or for a private patient) which can be provided—allowing for the best interests of the members—as well for the visiting staffs and others in their private capacity as in the hospital and some form of payment through the hospital for treatment at a hospital for the club members in all other instances.

It has been the case that the opinions of the public press would be more likely to be correct and medicine would be relieved of its late incubus—I am, etc.,

E RO LAND FOTHERGILL

A CLINIC FOR PHYSICAL TREATMENT IN  
LONDON

SIR,—In view of the prominence given in your issue of November 12th (p. 893) to a proposed clinic for physical treatment in London, may I draw attention to the fact that at the Physical Treatment Centre, Kensington, an attempt has already been made to meet the deficiency referred to in the article.

In a footnote three typical cases from the clinic at Amsterdam are quoted to indicate the need for physical treatment centres. Our case sheets could provide similar cases by the score, if not by the hundred.

All the ordinary forms of physical treatment are carried out here with the solitary exception of hydrotherapy. In the article mentioned it is said, "Such clinics have proved their value in other countries." I think we may justly claim that this clinic has proved its value in London, and at the present moment we have well over two hundred cases attending regularly for treatment—this without any official recognition from any approved society.

The clinic was founded to meet the necessity of providing physical treatment for those who are ineligible, or socially unsuitable, for a hospital clinic, and who are yet not in a position to secure the treatment privately. We also provide evening treatment so as to enable patients to come to us without interfering with their work. The numbers who avail themselves of this opportunity are ample proof of the need. The rules of this clinic are:

1. No patient is accepted for treatment unless recommended by a qualified medical practitioner.

2. No patient receives treatment until after examination by one of the medical officers of the clinic, who sees the patient with the manager, and prescribes treatment, and communicates with the patient's practitioner.

3. All treatment is carried out by a fully qualified staff who all possess the three certificates of the Chartered Society of Massage and Medical Gymnastics.

4. All patients must report for periodical examination by the medical officers of the clinic.

5. Before treatment commences all patients must satisfy the fully trained almoner that they are not in a position to pay full consultation fees, or for the carrying out of the full treatment prescribed over an adequate length of time by a qualified manager in private practice. The maximum fee payable for treatment is five shillings, but each patient is suitably assessed by the almoner. Some applicants are referred back to their doctor as unsuitable for institutional treatment, others are sent to hospital, but a very large field is covered between the two classes.

6. All patients are treated by appointment, and are therefore charged for treatment, unless adequate notice is given of absence.

It is very much to be hoped that, at the proposed clinic, the first five of these regulations will be strictly enforced, and that a fully trained almoner may be employed to prevent abuse.—I am, etc.,

JAMES MENEVILL

Physical Treatment Centre, Kensington  
Division B.R.C.S., Dec. 2nd

## THE PHYSIOLOGY OF DEFAECATION

SIR,—Dr. A. F. Hurst (BRITISH MEDICAL JOURNAL, December 3rd, p. 1053) explains that each meal gives rise to peristalsis in the large intestine. True, but he goes on to state that the greater part of the contents of the intestines accumulates in the cæcæ colon till the early morning. This may be true of most "normal" people living on the devitalized diet that has become customary, but it is not the natural physiological sequence, this is proved by the habits of those native races whose diet is a natural one, and also by those of our own race who have adopted a natural diet (including wholemeal, fresh fruits, and solids at every meal). With them a call to stool occurs after each meal, and, if responded to, leads to a soft solid evacuation.

It is most fallacious to regard natural foods as irritating, they are nothing of the kind, they are merely mild mechanical stimulants of intestinal activity, and they achieve this mainly by their bulk. Fine intestinal irritants are soluble substances and the most potent are the products of putrefactive bacteria. These give rise to the chronic catarrhal state of the mucosa revealed with appalling frequency on making x-ray examinations of the

colons of persons living on the customary diet of starch, sugar, and overcooked protein. Bacterial toxins inhibit peristalsis in the colon and lead to the use of purgative drugs, which aggravate the intestinal catarrh, and thus create a vicious circle—I am, etc.,

London, W.1, Dec. 3rd.

ALFRED C. JORDAN

SIR,—Dr. Hurst is very complimentary to the scope of the influence of the New Health Society, even though its teaching, in his opinion, is having so disastrous an effect. Having been associated somewhat closely with the educative literature on diet issued by that society, I would like to point out that our teaching is based, primarily, on the necessity for obtaining a correct "balance" in the diet.

For this reason the more liberal use of green leaves, whole cereals, and fresh fruit has been advocated, and this teaching is based on the best knowledge that we possess of the essentials of good nutrition.

Clinical and laboratory experience show that the higher vitamin content (and possibly also the higher content of indigestible cellulose in these foods) plays an important part in securing healthy activity of the intestines. If this, as Dr. Hurst maintains, is unphysiological we are in somewhat of a dilemma. It must also not be forgotten that these particular articles of food have been freely used by humanity through countless generations, and that our present dietetic habits have existed during only a very small part of man's existence. It is very doubtful whether there has taken place any real adaptation to this change of habit. What has followed, however, is so great a prevalence of gastro-intestinal disorder that special clinics and a galaxy of surgical talent are called for to deal with it.—I am, etc.,

London W.1, Dec. 5th.

S. HENNING BLERICE

## DEVELOPMENTAL ANOMALIES

SIR,—In a memorandum in the issue of the JOURNAL of November 12th (p. 876) Dr. Richard H. Hunter describes in instance of a rare developmental anomaly in a newborn infant, and states that he has been unable to trace a record of any similar case. May I draw attention to a case of persistence of the cloaca which I observed and which was described in your columns on December 10th, 1921. Since that time I have had the opportunity of examining two additional cases of this condition. In one of these (1924), as in my original case, the abnormalities were almost identical with those described by Dr. Hunter, while in the other case (1922) there was an associated exomphalos and the anterior wall of the cloaca was incomplete. In all my three cases the large gut had a small but patent opening at its lower end, leading into the cloaca as above, but in none of them was there any anal opening. Dr. Hunter's case had a left-sided hydronephrosis. None of my cases had this, but one of them had slightly dilated ureters. In all of them, as in Dr. Hunter's case, the urethra was quite impervious. Dr. Hunter raises the question as to the period at which the kidneys begin to secrete. He will find some evidence on this point in papers published in 1923 and 1924 by E. E. Hewer and by Lucas Keene and E. E. Hewer.—I am, etc.,

Glasgow, Nov. 15th.

J. NORMAN CRUICKSHANK

## MOBILE LABORATORIES IN THE WAR

SIR,—I would like to say that I yield to no man in my admiration for the work of the late Adrian Stokes, but I cannot help thinking that it is a pity that his death should be made the occasion for a wrangle as to which of the two directorates of the Medical Department of the War Office—pathology or hygiene—was responsible for the first mobile laboratory to appear in the field in France in 1914. Colonel Lyle Cummins's letter (November 19th, p. 956) substantially agrees with mine in that Stokes was not associated with either of them (JOURNAL, October 8th, p. 660). It must be very plain to the onlooker that the two laboratories must have run a neck-and-neck race as to priority, and that the date of their appearance at St. Omer

is scarcely an adequate criterion. Coplins's hygiene laboratory crossed over to France on November 17th, and Rowland's bacteriological laboratory on October 14th. I respectfully say that this evidence hardly permits the validity of the suggestion put forward by Colonel Cummins—namely, that so great was the need at this laboratory [that is Rowland's] that the director of hygiene determined to have mobile laboratories on somewhat similar lines fitted up for the hygiene department. The time is all too short to warrant this assumption.

As Dr Coplins was also engaged at the Inter Institute as a voluntary worker on the outbreak of war and therefore a fellow worker of Rowland I have asked his opinion on the matter. He tells me that during the months of June and July, 1914, he was engaged in making a sanitary survey of the area which was afterwards the area of hostilities, and that on August 5th or 6th he was present at the War Office when the sanitary situation was discussed. During September he had 150 men of the 1st London Division under training for special service in connection with field water supply, and that the director of the Institute kindly gave facilities for instruction by placing the Institute's laboratories at his disposal. The matter of a special mobile laboratory had also come under consideration and the work of construction was given by the War Office to the Napier works at Acton. Owing to pressure there was considerable delay in delivery, and during this period the Inter Institute managed to obtain a ready-built motor caravan, which was fitted up and immediately dispatched under Lieutenant Rowland. The hygiene laboratory followed as soon as it could be completed. It will be seen therefore that the hygiene department of the War Office had not been in backward in the matter.

With regard to the epidemic of typhoid fever this took place amongst Belgian civilians living in Belgium. Colonel Cummins who is usually a accurate is in error in referring to the D.A.D.M.S. (Sanitation) Second Army in this connection, as this appointment was not created until some eighteen months later. Captain Coplins who was in charge of the hygiene laboratory was also appointed to act as my sanitary officer. He confirms my statement that Adrian Stokes took no part in the measure taken under my direction for dealing with this epidemic and state that neither before nor during the epidemic had he any communication with Stokes either directly or otherwise upon this or any other matter. This statement is sufficiently categorical and should dispose of the whole matter. I would emphasize however, that this outbreak occurred in Belgium and that the Second Army was at that time the only British force in that country. The measures for dealing with the outbreaks were undertaken solely by the authority of the Belgian Ministry of the Interior and I was named sanitary authority in this connection by the Governor of West Flanders.

The hospital mentioned at Malaisie (which is in France) the bacteriological work of which was carried out by Stokes and Cecil Clarke, first began to receive patients in February 1915—some time after the beginning of the outbreak. It so happens that by Belgian law only such patients could be transferred from Belgium to France as consented and therefore the class of patient transported was mainly convalescent. The Second Army dealt with about 2,500 cases of whom rather less than one-third were transferred to Malaisie for a time many being retransferred later to a Belgian hospital situated on the Canche in the neighbourhood of Montreuil. This was also a Belgian hospital situated at La Panne which received entire patients from the northern area including the left flank of the Second Army. There were also three hospitals receiving cases within the army area.

I am glad that Colonel Cummins is in agreement that the history of this epidemic should be fully recorded—I am, etc.,

ROBERT PORTER  
Lieut. Col. (Ret.)

Beckenham Nov. 20/20

\*\* Although ready to publish a correction of my matter of fact, we cannot find it time to continue this correspondence. The tone of the epidemic might we think, more properly be the had out of evidence.

## Medico Legal

LYNDALL & ALCOCK

ACTION FOR NEGLIGENCE AGAINST A SURGEON

*Heavy Damage in Case of Volkmann's Contracture*

At the adjourned Bristol Assizes last week before Mr Justice Sharrin and a special jury an action for damages was brought by Phyllis Evelyn Tyndall a minor suing through her next friend Joseph Williams and her mother against Dr Arnold Alcock of Gloucester for alleged negligence and unskilled treatment. The defence was a denial of negligence and an killed treatment and a counterclaim for twelve guineas for services rendered was made. Mr H. A. Hawke K.C. and Mr Odgers instructed by Messrs Le Brasseur and Oakley London and acting for the London and Counties Medical Protection Society appeared for the defendant.

Mr Holman Gregory for the plaintiff stated that on July 6th 1920 the child Phyllis aged 8 fell from a donkey at Newent and fractured her left arm. She was taken in a motor car to Gloucester and was treated by Dr Alcock first at a nursing home and later in the Gloucester Infirmary. The arm became fixed at the elbow and Volkmann's contracture developed resulting in permanent impairment of movement. The child was said to be very intelligent and a brilliant musician, he had already passed three musical examinations and had performed in public. She would now be unable to play effectively any musical instrument. The mother had had to spend upwards of £80 on treatment and compensation was claimed on this count also.

In cross-examination Mrs Tyndall stated that she did not recognize that there was any greater danger in taking the child for a ten mile motor ride after the accident than in bringing her home. The arm was held very carefully during the journey. She denied that Dr Alcock had emphasized the serious nature of the case from the first.

Dr H. Chittly gave evidence that he had examined the child on October 14th 1926 and that there was then no voluntary movement of the wrist finger and thumb. She was suffering from fixation and contracture which usually arose from tight bandaging or splint pressure. He agreed that the fracture, though of the simple type was a comminuted fracture. By Mr Hawke he admitted that x-ray might be misleading and that more than one should be taken in various positions.

Dr F. J. A. Mayes radiographer at the Bristol Infirmary said that x-ray photograph of the child's arm showed that the fracture had not been reduced. Mr N. Duggan orthopaedic surgeon at Worcester Infirmary said that without a radiological examination at the time it was possible for a competent surgeon to overlook the condition of non reduction shown in the x-ray.

*Case for the Defence*

Mr Hawke K.C. opening for the defence claimed that the question was not whether there had been an error of judgement but whether Dr Alcock had done something which a person of ordinary standard in his profession would not have done.

Dr Alcock examined by Mr Odgers said that he was honorary surgeon to the Gloucester Infirmary and had been president of the Gloucestershire Branch of the British Medical Association. He had practised in Gloucester for eighteen years. When he examined the child after the accident he had found a fracture of the lower end of the humerus the fragments were in bad position the elbow slightly swollen and the ends of the bone were injuring the tissues. He manipulated the bones into position after which a green examination showed that the fragments were in alignment he was satisfied that the fracture had been properly reduced. The arm was then suspended from the shoulder and an x-ray photograph was taken. He had viewed the case seriously from the first and had explained this to Mrs Tyndall as tactfully as he could. The pulse and colour of the hand were normal at that time but the upper bony fragment almost protruded through the skin and threatened severe damage to other structures. Instructions were given that the circulation should be carefully watched. The next day the band was a little swollen and the bandages were loosened. On the fourth or fifth day there was more discoloration and Dr Alcock realized that the circulation was obstructed. The bandages were loosened and the strapping removed. Blisters were present but these were kept sterile and while the child was under his care no gangrene supervened. He suspected the possibility of Volkmann's contracture about July 14th or 15th and was certain of it by the third week of treatment. He told the mother that the child would be hopelessly paralysed. He knew that the fracture was lightly over reduced but he thought this advisable measure involved less interference with the blood vessel.

Professor Hey Groves of Bristol said that the diagram showed a severe fracture of the lower end of the humerus with satisfactory reduction or over reduction complete alignment was obtained and it was much more important to restore the circulation than to maintain alignment. He thought that Dr Alcock had adopted the proper course in his treatment. Other evidence in support of the defendant was given by Dr C. W. Knight orthopaedic surgeon at Gloucester Infirmary the main on the nursing home and a medical officer.

Mr Hawke addressing the jury on the defendant said that Dr Alcock could not be said to have erred in any necessary step and he had made radiological examinations in consultation with a skilled radiologist. It was admitted that as portions in diagrams

were not infrequent, and gave rise to errors of judgement. Mr. Holman Giggory, for the plaintiff, maintained that it ought to have been realized from the skidgram that something was wrong, and further attempts should have been made to reduce the fracture more perfectly.

**Verdict and Judgment**  
After the judge had summed up, the jury retired for one and a half hours, and returned a verdict that Dr. Alcock had not properly set the bone, and had failed to treat the case properly afterwards. The judge then explained that the verdict was incorrect, and that the jury had to return a verdict that the defendant was guilty of negligence, if he had shown in their opinion, an improper lack of skill. After a few minutes' absence the jury returned, and the foreman stated that a unanimous verdict had been found for the plaintiff, the damages being assessed at £2,000 for the daughter, and £150 for the mother. Mr. Odgers applied for a stay of execution, which was granted on condition that the costs of the action and £500 were paid into court by the defendant.

## Universities and Colleges.

**UNIVERSITY OF LONDON**  
Dr NEVILL'S FENZ has been recognized as a teacher of radiology at St Bartholomew's Hospital Medical College.  
The examination for the academic diploma in Bacteriology will commence on the first Thursday in July instead of the first Monday the regulations (Red Book, 1927-28, p. 513) are to be amended accordingly.

Sir Wilmot Herringham, KCMG, MD, has been elected chairman of the Library Committee.  
The following are constituted the Boards of Examiners for the first examination for medical degrees, together with the External Examiners of the respective boards being indicated by an asterisk.  
*Organic Chemistry*—H. J. Evans (University College) and \*C. S. Gibson (Guy's Hospital Medical School).  
*General Biology*—\*G. P. Mudgo (East London College) and London School of Medicine for Women) and W. A. Cunningham (St. Bartholomew's Hospital Medical College) or failing him, F. E. Fitch (East London College).  
*Physics*—W. H. White (St. Mary's Hospital Medical School) and J. L. Cuthbert (East London College).

**UNIVERSITY OF DURHAM**  
Sir THOMAS ORRILL, MD, LL.D., FRCP, president of the College of Medicine, Newcastle upon Tyne, has been appointed Vice-Chancellor of the University of Durham, in succession to Professor P. J. Heawood.

**UNIVERSITY OF LIVERPOOL**  
At a meeting of the University Council held on November 29th, a bequest was reported under the will of the late Eminent Professor W. Thielwall Thomas, FRCS, of £5,000, to endow a Fellowship in surgical pathology.

**UNIVERSITY OF ABERDEEN**  
At a special graduation held on November 29th the following diplomas were conferred:  
D.P.H.—Catherine H. Baxter, Ethel R. Dmshe, Winifred M. Foster, Grace M. Robinson and Emd. O. Olive.

**UNIVERSITY OF DUBLIN**  
SCHOOL OF PHYSIC, TRINITY COLLEGE  
The following candidates have been approved at the examination indicated:

**FINAL MEDICAL EXAMINATION Part II Medicine (MB)—A. R. Ewart, J. L. Wells, K. Watson, E. M. Gamble, J. R. Hanna, G. H. Henry, J. H. Stephens, L. R. Brumby, Wilfreda D. C. T. Piggott, H. S. North, Christina M. Donald, Surgery (B.Ch.)—R. R. Woods, J. K. Harper, G. M. Donald, Smith, Ethel M. Wen, J. H. Stephens, G. H. Hony, A. R. Ewart, I. Isaacs, R. M. Moore, \*A. G. Morgan, \*I. R. F. Twoody, R. I. G. Reid, Marie V. E. Lon, Wilson, H. J. Robinson, J. K. Harper, H. E. Knott, F. G. Stewart, C. R. Harris, J. Horwich, R. F. W. K. Allen, W. Crawford, G. W. F. Pratt, D. K. Walsh, A. C. G. Ffolliott, F. O. W. A. Mahon, D. J. Wells, E. C. Hicks, G. Q. Chance.**

**DIPLOMA IN GYNAECOLOGY AND OBSTETRICS**—Ann Macleod.  
\* Passed on high marks.

**ROYAL COLLEGE OF PHYSICIANS OF IRELAND**  
At the monthly meeting of the Presidents and Fellows, held on December 2nd, the President duly admitted to the Licences in Medicine and Midwifery of the College the following candidates who had passed the Winter Final Examination under the Conjoint Scheme of the Irish Royal Colleges of Physicians and Surgeons:  
W. Bannan, J. J. Bouison, J. Chambers, J. Clom, L. S. Clifford, J. P. Egan, F. N. Eleod, J. J. Golding, J. L. Miller, May, F. M. Carthy, P. L. O'Neill, Sarah M. O'Neill, J. C. Richardson, A. Stein, F. W. Warren.  
Dr. R. L. Micks was elected as Deputy for the King's Professor of Veterinary Medicine and Pharmacy to act as Clinical Physician to St. Patrick's Hospital.  
A letter was read from the President of the Royal College of Physicians of London asking the College to appoint a delegate to the Harvey Tercentenary Celebrations in 1923. In accordance with the unanimous wish of the College, the President (Dr. William Arthur Winter) consented to act.

## Obituary.

Dr. WALTER CHARLES ORRILL, who died on November 28th, at the age of 52, received his medical education at Trinity College, Dublin, where he graduated MB, B.Ch., B.A.O., in 1900, and proceeded M.D. five years later. He was a senior moderator and gold medalist of his year. A colleague at the Northern Hospital, Liverpool, writes: "Orriam came to Liverpool in 1904 after a distinguished career at Trinity College, Dublin. He had the same natural bent himself, and at Trinity College he graduated B.A. in physics and chemistry. He devoted his talents to this study from the first and came to Liverpool to take charge of the electrical department of the Skid Hospital. His work for which he was naturally fitted. At first he combined this work with general practice, but after a few years he obtained important hospital appointments and confined his attention entirely to radiology. From this time he did a phenomenal amount of work in the voluntary hospitals to which he was attached, the Northern Hospital and the Stanley Hospital in Liverpool, and the Infirmary in Southport owe him a very deep debt of gratitude for years of devoted service. With this hospital work he combined a busy private practice, and there is no doubt in the minds of those who knew him well that he persistently overtaxed a physique which was not naturally very robust. He gave himself few holidays, and those few he often cut short because of some duty which he fancied he was neglecting or not completely fulfilling. I have known him to plan a fortnight away, and then, after a week, to think of some batch of reports or other work waiting to be completed, and to return because of this before the seventy-fourteen days were over. This was characteristic of the man, a devotion to his work which did not allow him to spare any pains or energy. At the time of his death his hospital appointments were physician-in-charge of the radiological department of the Northern Hospital, honorary radiologist to the Stanley Hospital, honorary radiologist to St. Paul's Eye Hospital, and radiologist to the Southport Infirmary. This catalogue is an indication of the amount of voluntary work which he continued to do. In 1912 he was secretary of the Section of Electro-Therapeutics at the Annual Meeting of the British Medical Association in Liverpool. During the war he was on the staff of the 1st Western General Hospital, and for six months was with the 57th General Hospital in France as radiologist. His death at the early age of 52 was due to the overtaxing of his physical powers. His many friends will remember him as a man whose modesty and devotion were the outstanding features of his life, that he would never have been able to put on record the fact of work which he gave to the public service without the expert assistance of an able and devoted wife.

Dr. JOHN PRIOR PURVIS, who died on November 18th, was born in 1841. In 1859 he entered as a student the Dicednought hospital ship, and in the following year joined St. Thomas's Hospital. In 1863 he obtained the diplomas MRCS Eng. and L.S.A., and was then appointed house-surgeon to the West Herts Infirmary, Hemel Hempstead. In 1867 he joined his father in practice at Greenwich, and two years later was appointed medical officer to the Royal West Kent Dispensary, which subsequently became the Miller General Hospital, on his retirement from this institution in 1925 he was elected an honorary governor. In 1885, in conjunction with Miss Christabel Orrill, he established the Greenwich Provident Dispensary, and remained one of its medical officers until his retirement in 1925. In 1870 he had been appointed public vaccinator, and he held this post until his death. He

took great interest in the 2nd Volunteer Battalion (Queen's Own) Royal West Kent Regiment, and was awarded the Volunteer Decoration. He lectured for the St John Ambulance Brigade for many years and was an honorary associate of the Order of St John of Jerusalem. He succeeded his father as treasurer of the West Kent Medico-Chirurgical Society, and held the post for thirty years. He similarly followed his father as chairman of the Greenwich Industrial Permanent Building Society. He was a member of the executive committee of the Greenwich Division of the British Medical Association in 1911, and from 1914 to 1921, he was chairman in 1913. Dr Purvis leaves four children, twelve grandchildren, and two great-grandchildren.

Dr LEO NORTON KNIGHT O'NEILL, who died on November 22nd in the Norfolk and Norwich Hospital, after a short illness, was born in 1880 and was educated at King's School, Canterbury, and Exeter College, Oxford, where he graduated B.A. in 1913. Prevented by a cycle accident from serving as a combatant in the war, he entered Durham University College of Medicine in 1915 and was appointed surgeon probationer in the navy in 1918, serving until the end of the war in H.M.S. *Blower*, which was the first allied ship to pass the Dardanelles after the armistice. After demobilization he resumed medical study, and graduated M.B., B.S. Durh., in 1922. He held hono appointments in the Royal Victoria Infirmary, Newcastle-on-Tyne, and was resident medical officer of the Kent and Canterbury Hospital. In 1925 he began practice in partnership at Great Yarmouth. Dr O'Neill was an enthusiastic yachtsman and knew the south coast of England very well.

Dr HENRY ERNEST KNIGHT of Rotherham died on December 2nd. The son of a doctor, he was born at Rotherham in 1866 and from the local grammar school went on to Epom College and St Bartholomew's Hospital. In 1889 he took the diplomas of the English Conjoint Board and also graduated M.B. Lond., and five years later proceeded M.D. Before returning to practice in his native town he had served as house physician and assistant electrician at St Bartholomew's Hospital and house-surgeon to the Stockton and Thornaby Hospital. He was president of the Sheffield Medico-Chirurgical Society in 1911-12 and was a member of the Rotherham Division of the British Medical Association. In 1915 he was appointed a justice of the peace and in the same year was elected a feeoffee of the common lands of Rotherham. He had also held the office of greive. Dr Knight was formerly honorary surgeon to the Rotherham Hospital but when extensions were opened he accepted the position of honorary physician.

Dr CHARLES CORMACK GREIG died recently in his eightieth year at his native town of Fyvie. He was educated at Aberdeen University where he graduated M.B. C.M. in 1875 after which he continued to carry on his father's practice up to the time of his death. He was parochial medical officer and public vaccinator for Fyvie and Anechures, medical officer to the Fyvie Cottage Hospital and a member of the Aberdeen Division of the British Medical Association. Dr Greig was for many years an enthusiastic volunteer; he joined as a private of the Fyvie Company of the 2nd Volunteer Battalion, Gordon Highlanders in 1874, became acting surgeon of the same company in 1875, was promoted surgeon-major in 1880 and surgeon lieutenant-colonel in 1895 in which year he received the Volunteer Decoration. He was appointed lieutenant-colonel R.A.M.C.F. in 1908. Two daughters survive him.

Dr ROBERT DUNSTON died in London on November 27th following an operation; he was 79 years of age. He received his medical education at Queen's Hospital Medical School and took the diploma of L.S.M. in 1871 and M.R.C.S. in 1872. He served as surgeon to the Pughton Cottage Hospital and medical officer in charge of troops at Pughton. He was an enthusiastic chess player and repudiated over 100 times his last match being for Sussex only a short time before his death.

## Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

THE House of Commons has been chiefly occupied this week with the Unemployment Insurance Bill.

In the House of Lords, on December 6th, the Marquess of Salisbury made a statement about the business which the Government hoped to get through before Christmas. In addition to the principal Government measures there were some others which it would be in the interests of the country to get through it possible. Among these were the Mental Deficiency Bill and the Nursing Homes Bill. These bills were not yet through the House of Commons but if they were quite non contentions in the House of Lords perhaps the Government might ask them to agree to them.

In the House of Lords on December 6th the Royal Edinburgh Hospital for Mental and Nervous Diseases Order Confirmation Bill was read a third time and passed.

### The Future of Voluntary Hospitals.

Mr. Poy Wilson asked the Minister of Health on December 1st whether in his proposals for the reform of the Poor Law and reorganization of the health services of the country he contemplated that the voluntary hospitals should come under the control of the State or the local authorities. Mr. Chamberlain answered that on the contrary he regarded the preservation of the voluntary hospital system as a matter of essential importance in the health interests of the country. What had been impressed on his mind was the absence at present as a general rule, of any systematic arrangements for co-operation between the voluntary hospitals and the hospital and institutions carried on by the local authorities. He had therefore suggested that it was advisable that there should be consultation in the various areas with a view to arriving at an agreed plan for institutional provision which would enable each kind of hospital to play its proper part in meeting the ever increasing need of the people for hospital accommodation. He anticipated that under such a plan the position of the voluntary hospitals would be strengthened and not weakened but he had never contemplated putting any compulsion upon them to come into an arrangement their participation in which would be a matter for their own determination. During the past twelve months the voluntary hospitals had responded in an astonishing manner to the requirements of the country and while at one time it had appeared to be impossible for them to meet the need for extension they were now largely overcoming that difficulty. Not only had they been able to find in most cases sufficient money for the maintenance of existing beds but they had been able to make very considerable additions.

### The Frils of Slums.

In the House of Lords on December 5th the Bishop of Southwark asked when the Government proposed to introduce legislation to facilitate the clearance of slums in London. The London County Council had schemes relating to about 91 acres which would affect 25,000 people out of it was estimated that 11,000 houses containing a population of over 300,000 were in slums. The extent of the slums meant that a very large portion of the population had to grow up under conditions in which health was almost impossible and where character as well as physique was almost bound to deteriorate. Many reformers believed that a great deal could be done to rectify on many houses in the slums were purchased by the local authority. Slum clearance was of course the ideal solution but some temporary measure as he suggested might be necessary. The Bishop of London said that overcrowding was the parent of disease. People could not be expected to live healthily in such conditions.

Viscount Gage replying for the Government said that the creation of some 100,000 new houses since the armistice must have relieved the evil of overcrowding and the progress made in slum clearance having regard to the difficult circumstances could be described as encouraging. His slum schemes had been confirmed by the Minister of Health and others were under consideration. Apart from the wholesale clearance of large slum areas local authorities were paying constant attention to the condition of individual houses in their district. The reports of the medical officers of health for 1925 showed that 111,000 houses had been inspected by officers of the local authorities. Of these 105,000 were rendered fit by the owners after notice of statutory notices were made up by the local authorities in 1925 and of the owner and defects were remedied in the case of 279,000 houses without the need of formal action. Thus the local authorities were able to get repairs in 82,000 cases during the last year. The Minister of Health however considered that the slum problem was not being dealt with in a sufficiently comprehensive manner and that considerable improvement would be effected within a reasonable time. There was no doubt that the slum problem was a national one and was being dealt with in a comprehensive manner and was being dealt with in a comprehensive manner and was being dealt with in a comprehensive manner.

authorities would be in a position to turn their attention in a greater degree to the slums. Although the powers of local authorities for dealing with slums were wide, it might be possible to introduce a further measure whereby houses in an unsatisfactory area, which might be saved by the expenditure of a little money, would be reconditioned, and only houses which were past redemption would be demolished. Another matter on which the Minister had promised to legislate was in regard to the basis of compensation for immovable property acquired in connection with slum schemes, but the time or nature of the legislation could not at present be stated.

**National Health Insurance**—In an answer given on December 1st to Sir Richard Luce, Mr. Chamberlain said that the recommendations of the Royal Commission on National Health Insurance had been exhaustively discussed with the consultative council or approved societies, and the Government intended to take the first convenient opportunity of introducing an amending Health Insurance Bill embodying most of the recommendations of the Commission. It did not, however, propose to provide in this bill for the abolition of Insurance Committees or for the extension of medical benefit to include a specialist and consultant service by means of a partial pooling of societies' surpluses.

**Small pox**—The Minister of Health stated, on December 6th, that the number of cases of small pox notified in the city of Lincoln during the three months ended November 26th was 33. He was informed that with a view to preventing overcrowding of the small pox hospital a ward block at the isolation hospital, separated from the remainder of the hospital by a fence, was being used for the treatment of small pox patients.

**Inspection of Offices**—Dr. Lumsden asked Mr. Chamberlain on December 1st whether his suggestion that metropolitan borough councils should carry out a systematic inspection of offices had been adopted, and if so whether any assistance to such inspection had been offered on which a test case could be prepared on the power of local authorities over office sanitation. Mr. Chamberlain said he had not issued any communication to the metropolitan borough councils on the subject. He was informed that systematic inspection was made in a few of the boroughs, and he had not heard of any case of resistance.

**Notification of Tuberculosis**—In a reply to Dr. Vernon Davies, Sir Kingsley Wood said the Minister of Health was not yet satisfied that the early notification of tuberculosis had been secured in all parts of the country. The Ministry had issued circulars to medical practitioners and to local authorities on the subject which would be again considered on receipt of the notification returns for the present year.

**Rinderpest and Foot-and-Mouth Disease**—On November 30th Dr. Vernon Davies called the attention of the Minister of Agriculture to the fact that the United States of America had restricted the import of South American meat from some areas infected with foot and mouth disease. Dr. Davies asked whether the Minister of Agriculture would discuss the matter with the Minister of Health to ensure that the health of the people of this country was safeguarded. Mr. Guinness replied that the United States Department of Agriculture Order of September 17th 1926, to which Dr. Davies referred prohibited the import of fresh or frozen meat from countries where rinderpest or foot and mouth disease existed. It appeared to be designed to protect animals as human beings did not suffer from rinderpest. Practically all meat imported into Great Britain from South America was inspected in the country of origin and was subject to further inspection on arrival. Dr. Davies asked whether the Ministry of Agriculture thought there was no danger to human beings in admitting to this country meat which might be contaminated with foot and mouth disease. Mr. Guinness said that it is the practice was to cook meat before eating it he did not think there was much danger. Recorded human cases of foot and mouth disease had been traced to milk or to contact with diseased animals. He thought there was no evidence against cooked meat. The Government was negotiating with the South American Governments to induce them to undertake special regulations for preventing the introduction of disease into this country.

**Tuberculosis Officers and Private Fees**—Sir K. Wood, on December 6th, said that the public health committee of the Devon county council had passed a resolution which in effect stated that they wished to make it clear that the services of tuberculosis officers were absolutely free to all classes of the community, and that in no case could remuneration be made to them in any form. A copy of the resolution had been sent to the officers concerned but no other steps had been taken to make it public. The Minister was informed that the resolution was passed because it was reported to the committee that one or more of the tuberculosis officers of the county council had received fees or presents from individuals visited by them in their capacity of tuberculosis officers.

#### Votes in Brief

On December 5th Earl Winterton replying to a question said that all cocaine used in India was imported. Its importation was subject to the closest control but the illicit traffic could not be successfully stopped except with the co-operation of manufacturing countries.

The Geneva Opium Convention of 1925 has been ratified by France and Poland and for all parts of the British Empire excepting Canada and the Irish Free State.

The Ministry of Health does not feel justified in contemplating the treatment of rheumatism by a general scheme on the lines of that adopted for tuberculosis.

The Minister of Health offers to arrange for any Member of Parliament who wishes to do so to visit the Government lymph establishment.

A report on the provision made in Lambeth Infirmary for isolation and observation purposes is being prepared by a medical officer of the Ministry of Health.

Asked about the statement alleged to have been made at an inquest in Sheffield by a medical practitioner, to the effect that the best thing he could do was to let a man die as if he had lived his life would only have been a misery, Sir Thomas Inskip, the Solicitor General, said the inquest had been adjourned for a post mortem examination, and it was impossible for him to answer questions on the case.

Mr. Omsby Gore states that there is little prospect of an effective reduction in the amount of opium smoked in Malaya so long as unlimited supplies are available in China and continue to be smuggled into the Colony.

The Home Office knows of no case of poisoning due to the use of petrol containing tetra ethyl lead.

Mr. Chamberlain sees no reason for instituting an inquiry into the administration of mental hospitals.

The Minister of Health has ordered the publication of reports of the inquiries into the conditions of the production and manufacture of condensed milk in Holland and Denmark, so far as they affect public health.

## Medical News.

IN commemoration of his jubilee as a general practitioner Dr. James Murray of Inverness has been entertained at a complimentary dinner by his colleagues from various parts of Ross shire and Inverness shire, who presented him with a silver salver. The chairman, Dr. J. W. Mackenzie (Inverness) said that Dr. Murray belonged to the credit of being the first to introduce antiseptic surgical treatment in the Northern Infirmary, for which he was well qualified by his training under Lister. Dr. Murray, in acknowledging, referred to the fact that he graduated at a time when the immortal discoveries of Pasteur and Lister completely revolutionized the practice of medicine and surgery. It was his good fortune to be closely associated with Lister as a prize man and as a student.

THE Master and Wardens of the Society of Apothecaries have issued invitations to a dinner at Apothecaries' Hall, Blackfriars, on Tuesday, January 31st, to meet the Lord Mayor and Sheriff.

THE Australian and New Zealand Medical Association in England will hold its winter dinner on December 16th, at 8 p.m., at the Trocadero Restaurant, Piccadilly. The High Commissioners of Australia and New Zealand will be the official guests. All medical visitors are invited. Further particulars can be obtained from the honorary secretaries, Drs. D. T. C. Milligan or H. Bedford Russell (85, Mark Lane Street).

MR. ERNEST CLAPKE will give the last of the present series of lectures arranged by the Fellowship of Medicine, at the Medical Society of London, 11, Chandos Street, on December 12th, at 5 p.m. His lecture, which is entitled "Practical hints in the correction of errors of accommodation and refraction of the eye," is free to medical practitioners. The special courses arranged by the Fellowship of Medicine for January are medicine, surgery, and the specialties at the Prince of Wales's General Hospital, cardiology at the National Hospital for Diseases of the Heart (limited to 20, so early application is desirable), diseases of children at the Children's Clinic, and psychological medicine at the Bethlem Royal Hospital. Syllabuses, tickets, and specimen copies of the *Post Graduate Medical Journal* may be obtained from the Secretary of the Fellowship, 1, Wimpole Street, London, W.1.

A SERIES of lectures and practical courses of instruction for a diploma in psychological medicine will commence at the Maudsley Hospital, Denmark Hill, S.E.5, on January 4th, 1928. Part I of the course will consist of twelve lectures by Dr. F. Golla on the physiology of the nervous system, with demonstrations on the physiological psychology, six lectures and demonstrations on the biochemical aspects of mental disorders and laboratory methods, by Mr. S. A. Mann, B.Sc., F.I.C., eight lectures by Professor G. Elliott Smith, M.D., on the anatomy of the nervous system, practical instruction and demonstrations by Mr. Charles Geary, and eight lectures and demonstrations by Dr. Henry Devue. Part II, commencing in March, will include lectures and demonstrations on psychoneuroses, morbid psychology, the pathology of mental diseases, pathological anatomy, the legal relationship of insanity and treatment, mental deficiency, crime and insanity, therapeutics, clinical psychiatry, neurology, and the abnormalities of the fundus oculi. The fee for the whole course

is £15 15s, and for Part I and II separately £10 10s each. Inquiries should be addressed to the Director of the Central Pathological Laboratory, Maudsley Hospital, Denmark Hill, S.E. 8.

A THREE months course of lectures and demonstrations on clinical practice and hospital administration for the diploma in public health will be given at the North Eastern Hospital, St. Ann's Road, Tottenham, by Dr. F. H. Thomson, medical superintendent, on Mondays and Wednesdays, at 4.45 p.m., and alternate Saturdays, at 11 a.m., commencing on January 4th, 1928.

INTERNATIONAL medical courses will be held in Berlin during March and April, the subjects including new aspects and methods of clinical pathology and therapeutics, recent discoveries in connection with metabolic disorders, obstetrics and gynaecology, and radiology. In addition to this there will be several series of lectures and demonstrations in different medical subjects throughout the winter. The courses are held in German, but some of the professors lecture also in English, French, and Spanish. Further information may be obtained from the secretary, International Medical Continuation Courses, Kaiserin Friedrich Haus, Luisenplatz 2-4, Berlin, N.W. 6.

THE out-patient department of the Princess Louise Kensington Hospital for Children was opened on December 6th. It contains accommodation for orthopaedic, ophthalmic and oto-rhino-laryngological diagnosis and treatment, and there are also electrical and x-ray rooms. It is hoped that thirty six beds will be available for in-patients early in 1928, some of these will be reserved for school children requiring tonal operations. A good operating theatre with all the modern surgical appliances, is to be provided. The hospital represents the re-establishment of a small institution in Church Street Kensington on which was founded in 1840. It is situated in a very congested area in North Kensington. The funds for its establishment have been collected during the last three years by a committee under the presidency of Princess Louise and the King and Queen have promised to open the hospital formally next May if the cost of £12,000 for the out-patient department and the two first ward blocks has been met by that date. A list of the honorary medical staff appears in the SUPPLEMENT under the heading 'Appointments'.

A NEW women's hospital, which has been erected by the Warial Board of Guardians at a cost of £30,000 was opened at Clatterbridge on November 24th. It provides accommodation for 112 beds. The lower floor is occupied by the surgical section and the upper is devoted to medical cases, with special wards for fevers. Provision has been made for private patients.

THE council of Ipswich College is about to award a St. Anne's Home Scholarship of £52 a year to the orphan daughter of a medical man who was in independent practice in England or Wales for not less than five years. Candidates must be not less than 7 and not over 12 years of age on May 1st next. Forms of application can be obtained from the secretary at the office of the College, 49, Bedford Square, W.C.1.

MR P. C. RAINMENT M.A. Oxon, M.R.C.S., L.R.C.P., has been appointed to the vacant chair of physiology in the State University of Egypt at Cairo. Mr. Rainment who took first class honours in the Natural Science School at Oxford has been for the last six years university demonstrator in biochemistry at Oxford. He leaves England at the end of this year.

THE Scottish Board of Health have appointed Dr. James L. M. Symms to be a District Medical Officer (Medical Referee) in their department.

THE annual report for the year 1926-27 of Livingston College, Leyton, shows that nearly 1,000 missionaries have received instruction there since its foundation in 1900. During the year under review 100 students, attended representing twenty-eight missionary societies and seven countries. The instruction given included a full session from October to June comprising, elementary physiology, anatomy, practical medicine, surgery, tropical medicine and hygiene, a vacation course in July and three short intensive courses in March, September and December on the care of health in the tropics. We referred to the Commemoration Day celebrations on June 18th (p. 1133).

THE health conditions at Port of Spain, the capital of Trinidad, are summarized for June last by Dr. George H. Vasson, medical officer, in his report to the City Council. Of 114 deaths which occurred nearly one half were in public institutions. Tuberculosis, bronchitis, and enteritis were each responsible for 8 deaths and deaths were recorded also from pneumonia, malaria, dysentery, and syphilis. Four cases of typhoid fever were notified, and 990 cases of pits were oiled and disinfected as a preventive measure. Three railway cars were disinfected for leprosy. The rats destroyed numbered 555,

all were free from plague. Of 2,717 premises inspected for mosquitoes most were satisfactory, but in 194 larvae were found. The sanitary administration of Port of Spain presents a varied interest.

PROFESSOR CALMETTE, sub-director of the Institut Pasteur, has been elected a member of the Académie des Sciences.

PROFESSOR GOSSET of Paris has been elected president, and Professor Tixier of Lyons vice president of the French Congress of Surgery to be held in 1928 when the following subjects will be discussed: (1) spinal anaesthesia introduced by MM. Forgue of Montpellier and Basset of Paris; (2) remote results of the surgical treatment of nodular ulcer, introduced by MM. Delore of Lyons and Okunev of Paris; (3) remote results of trephining for traumatic lesions, introduced by MM. Milsonnet and Petit Dubaille of Paris.

THE *Gazette des Hôpitaux*, otherwise known as *La Lancette Française* has recently celebrated its centenary.

THE first International Oto-Rhino-Laryngological Congress will be held in Copenhagen under the presidency of Professor E. Schminckel on July 29th to August 1st, 1928, the official languages being English, French and German. The subjects to be dealt with include the conservative radical operation in chronic middle ear suppuration, epistaxis of pharyngeal origin, surgical diathermy in malignant growths of the upper air passages, and the anatomical structure of the middle ear and its influence on suppurations. Further information may be obtained from the general secretary, Dr. V. H. Biegrad, 3, Nytorv Copenhagen K.

IN 1926 there were 383 women medical practitioners in Vienna as compared with 326 in 1925, which represents an increase of 20 per cent as compared with an increase of only 2 per cent in the number of medical men. The total number of medical practitioners in Vienna is 3,688 so that the proportion of women among them is 10 per cent. Last winter session the number of women medical students had risen to 351, or 15 per cent of the total.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to THE EDITOR *British Medical Journal*, British Medical Association House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1 on receipt of proof.

All communications with reference to ADVERTISEMENTS as well as orders for copies of the *Journal* should be addressed to the Financial Secretary and Business Manager.

THE TELEPHONE NUMBERS of the British Medical Association and the *British Medical Journal* are: MUSLIM 57 5 9 3 9 3 and 9 6, (internal exchange four lines).

THE TELEGRAPH C. ADDRESS is as follows.

EDITOR OF THE *BRITISH MEDICAL JOURNAL*, *Artology* Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisement, etc.) *Articulate* Westcent London.

MEDICAL SECRETARY *Meducra* Westcent London.

The address of the Irish Office of the British Medical Association is 16 South Frederick Street, Dublin (telegram: *Bacillus Dublin*) telephone 4337 (Dublin) and of the Scottish Office 6 Drumhugh Gardens, Edinburgh (telegram: *Associate Edinburgh*) telephone 24351 (Edinburgh).

## QUERIES AND ANSWERS

"T. W. P. inquires whether tea without the alkaloids is as safe as coffee without caffeine."

### UPPER STAIR

R. H. W. writes in answer to a question about removal of urine stains from clothes (September 24th p. 573). I can recommend prolonged oiling of the cloth in cold water. The water should be changed from time to time and if the stain is old three or four days oiling may be necessary, but your correspondent will find that the stain can be very much reduced if not entirely removed.

### WORDS

Dr. ALEX. E. POCHI (London) writes, Dr. Herbert Smith in the *British Medical Journal* (December 3rd p. 1062) says that laparotomy should be lapara mysis comes from *lapara* (no *my*) On his quiet and reasonable reasoning the *al* *tra* *re* *coelothomy*, which he prefers should be *coelomy*, since it

## LETTERS, NOTES, AND ANSWERS

[THE BRITISH  
MEDICAL JOURNAL]

*sonico* is *κοιλια*, a word vainly meaning belly, stomach, or intestines and therefore probably less suitable for surgical terminology than *λαπαρη*, which denotes the superficial soft parts between ribs and hips—a favourite target of the Homeric heroes, whose guts prolapsed through wounds of it. In any case, *laparo* is sanctioned by usage.

## SINU-ITIS

Dr A B KIRK WILKINS (Nowcastle, N.S.W.) writes with reference to a letter by Dr Sydney Perry of Melbourne (JOURNAL, September 14th, p 518) to say that he has given colloidal man- ganose an extensive trial using different preparations in various doses with the disappointing result that no cases of definite frontal or sphenoidal sinusitis were cured or more than temporarily improved except in children, where a few examples of low grade nasal infection with a discharge, chiefly mucoid, completely cleared up. Dr Keith Watkins asks for information on the following points: (1) Which particular preparation of colloidal manganese does Dr Perry use? (2) How he determines the dose frequency, etc. in each case? (3) What accessories treatment he gives? (4) How long he keeps his cases under observation before a cure is pronounced? Dr Keith Watkins adds that he has found the greatest help, apart from operation, from the use of autogenous vaccine.

## A PERSONAL EXPERIENCE OF SPINAL ANAESTHESIA

"H B P" writes: After reading (November 12th, p 878) the report of the discussion at the meeting of the Section of Anaesthetics of the Royal Society of Medicine it occurred to me that my experiences as a medical man, after an operation in the course of which spinal anaesthesia was procured may not be without interest. I am a medical man, 1926 when 66½ years of age, I underwent complete removal of the rectum for carcinoma. I had general anaesthetic given and towards the close of the operation the thick was injected. Immediately following the operation I had complete retention of urine lasting for three weeks, at the end of which period this gave place to incontinence. After ten months I had complete control of the bladder by day, but the nocturnal incontinence still persists (twenty one months). In the first week in May 1926, I had a suprapubic cystostomy performed to relieve renal back pressure and for two months was normal in size. At present I have a urinary infection due to *B. proteus*. On recovering from the general anaesthetic I had no feeling in my legs neither could I move them for some hours after a few days when my legs and thighs commenced to atrophy. In May 1926 shortly after the cystostomy I found it difficult to extend my legs, which were flexed on the thigh at an angle of about 45 degrees. The question of forcible extension was then discussed but postponed as I was regarded as too weak for an anaesthetic. From this date on my legs gradually improved until in June 1926 I was able to stand and walk a little with assistance. In the spring of 1927 I walked slowly as much as six miles on end but since then I have slowly become more and more helpless until now I am completely confined to bed. At intervals since the operation I have had an irregular temperature. From a neurological standpoint the present condition of the limbs is: *Motion*. All movements of lower limbs absent. No muscle or tendon tenderness. *Reflexes*. Knee jerks absent, slight contraction palpable in quadriceps on extension; ankle jerks very slight. Plantars are flexor, and cremasteric reflexes absent. *Trophic*. No bedsores. Muscular tone very poor. Muscles extremely flabby. Thighs and legs wasted. The patient states that the right leg has always been the weaker but no difference was found on examination.

## PREVENTION OF EYE INJURIES

Dr J B PIER (Loughborough) writes: I have repeatedly striven at the Board of Trade and in the press to direct attention to the properly laws of injury to the eye by foreign bodies. The remedy, though obvious, is frequently overlooked. What seems to be required is that all engineering firms shall supply tinker glass protectors for the eyes, and that in case of accident due to the want of this simple precaution no compensation shall be awarded.

## INCOME TAX

"B H" deducted subscriptions to some professional societies which issue journals dealing with his particular subject, but the inspector of taxes has refused to allow the deductions, relying on Mr Justice Rowlatt's dicta in *Simpson v Tate*. Subscriptions to societies such as the British Medical Association, have, of course, been allowed. The case quoted dealt with an assessment under Schedule E, the governing section being Rules which allow the deduction of money expended "wholly exclusively and necessarily in the performance of the duties of the office or employment." "B H" is assessed under Schedule D and the relevant section, Rule 3 of (Cases I and II) is somewhat differently worded—"no sum shall be deducted in respect of any expenses not being wholly and exclusively expended for the purposes of the profession." It will be seen that under Schedule D the incurring of the expenses is not required to be "necessary." We suggest that our correspondent might remind the inspector

that Mr Justice Rowlatt was dealing with the stringent Schedule E rule and not with expenses allowable for Schedule D purposes, but we must admit that little, if any, emphasis was laid on the "necessary" stipulation, and the principle of Mr Justice Rowlatt's decision seems to have considerable application to Schedule D. At the same time it may well be that it is less rigorously applied in practice to Schedule D.

## CASH BASIS

"J J" explains that he is being pressed to supply particulars of his "earnings" as distinct from the excess of his cash receipts over payments made for professional expenses. The partnership deed requires the books to be kept on a cash basis. \* \* \* We have always understood the attitude of the Revenue authorities to be that while they regard the earnings basis to be technically correct—as we must admit it is—they are prepared to accept the cash basis as being equitable in the long run, and to consider that "J J" would be justified in pressing his point by requesting the hearing of his appeal by the district or the special commissioners. Two points should not be overlooked, one, that the cash basis is indefensible if the income of a particular year, as a single unit, is the important factor, as in the case of a new practice, the other, that on the basis of "earnings" a deduction should be made for specific debts believed to be wholly or partially irrecoverable.

## LETTERS NOTES ETC

Dr D OWEN WILLIAMS (Glandorf, Cardiganshire) writes: The memorandum about a cleft sternum (JOURNAL, October 15th, p 687) reminds me of two malformations of the sternum which I have seen during recent years. In one case the ensiform cartilage is considerably enlarged and thickened and feels hard, as if ossified, but of this I am doubtful, a doctor who saw it along with me some time ago thought that this was so, and that it was an exceptionally rare condition. In the other case the lower two thirds of the sternum are depressed being indented for at least 1 in in depth almost displacing the interior mediastinum and it is probably due to a rickety condition, although this is the only sign present in the chest.

## CROSSED LEGS AND DEFORMITY

Dr R TURNER (London, W.C.) writes: Having attended a very large number of newborn infants I have observed that the habit of crossing the legs in the lower third is very common among them and that the habit tends to persist. As a result the legs become bowed, and this condition is I think often mistakenly thought to be due to rickets as the child gets older. If the habit is counteracted at an early stage by the simple device of putting a small soft cushion between the infant's legs and feet the legs straighten early and easily.

## TREATMENT OF TONSILLITIS

Dr SYDNEY PERRY (Melbourne, Victoria) writes: Having for the last ten years been impressed by the enormous amount of sickness produced by infection in tonsils which in the past have been and still are, looked upon as normal I tried to find some method of cleaning up these infections, as, failing this, it meant that 75 per cent of the people would have to lose their tonsils. Being somewhat impressed by the work done by Drs Murphy, Witherbee, Craig, Hussey, and Stern at the Rockefeller Institute for Medical Research in 1919 I gave their treatment by doses of rays a trial, with varying results, to this I added exposures to ultra violet light to the tonsils and the high frequency current, the former to bring about local reaction the latter to help sterilize the surface of them. Vicines cultured from stabling the tonsils with a fine capillary tube helped, but of late I find that splitting down obvious crypts, keeping them open, and employing a solution containing iodine, 120, zinc iodine gr 160 cleaned up and remained healthy. As there are no nerves in the tonsils these crypts can be split without even cocainizing them, care being taken not to cut the anterior pillars of the fauces. I ray treatment is done once a fortnight on each side the rays being directed behind the angles of the jaws. The high frequency and ultra violet light treatment is employed thirteen weeks for the first few weeks then twice a week for eight or ten weeks. This is usually sufficient to complete the cure. Having done many hundreds now I am satisfied there are very few tonsils which cannot be freed from infection by these methods. The full details are published in the *Medical Journal and Record of New York*, August 17th 1927.

## VACANCIES

NOTIFICATIONS of offices vacant in universities medical colleges, and of vacant resident and other appointments at hospitals, columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43. A short summary of vacant posts notified in the advertisements columns appears in the Supplement at page 231.

## Observations

ON

## SOME POINTS IN CONNECTION WITH DETACHMENT OF THE RETINA

BY

SIR W. T. LISTER, K.C.M.G., F.R.C.S.

Consulting Ophthalmic Surgeon to the London Hospital  
Surgeon to the Royal London Ophthalmic Hospital

THE short time at my disposal I propose to devote to the important subject of the selection of those cases of so-called simple detachment of retina which are suitable for treatment, and to try to indicate which cases of this desperate condition give some reasonable chance of success.

I suppose we shall all agree that when both eyes are affected, or when the only seeing eye has developed a detachment, we may be driven to treatment which we know has little reasonable chance of success. We do this partly on the bare chance that our past experience may be upset and partly to make time so that our patient may have the satisfaction of feeling that something is being tried instead of suffering the double depression caused by the loss of sight and by a policy of hopeless inactivity.

But it is the question of treatment of a case of detachment of one eye only that I wish to discuss, for it is here that our colleagues appear to hold such divergent views. In spite of the articles which appear in the general press from time to time of the successful treatment which has been devised in this or that country, or even in the medical papers which publish reports of 100 per cent. of successes obtained in a modest series of a few units, we are all painfully aware that our chance of restoring sight with our present knowledge is very slight. When we consider the mental strain which our methods entail together with the considerable expense incurred in nursing, home and professional fees, only those cases where a reasonable chance of success exists should be subjected to treatment. Unsuccessful treatment is regrettable both from the disappointment and loss of money involved and also from the discredit to the reputation of the profession as a whole, as well as to the individual member who has advised it.

Some say the condition is hopeless whatever the cause and advise no treatment, some never advise anything beyond rest and the rest advised may be lying down for twenty minutes twice a day (as I know was advised in a well-known German clinic), or it may be complete rest in bed with the head raised from the pillow. Such treatment may be combined with constitutional measures and counter-irritation but no operation. Others again advise operative intervention at once. The majority I imagine advise rest, constitutional treatment and counter-irritation first and it is this, the unsuccessful resort to operation.

I have reason to think that quite a large number of cases of detachment are treated on a purely routine plan without sufficient endeavour being made to find the cause it is against such a course I chiefly wish to direct my remarks.

Though in many cases we know little or nothing of the actual mechanism of the detachment, in others we understand or can make a reasonable guess at it. Now it is surely on the particular mechanism of the detachment in any individual case that the reasonableness of our intervention mainly depends. I think it is correct to state that the retina is either "pushed in" from without or "dragged in" from within or "floated in" when there is a hole.

When the retina is dragged in by cicatricial bands, in the retina itself, as in retinitis striata, it seems to me that treatment can be of no avail and it should not be advised.

When the retina is being dragged in by visible bands in the vitreous we must distinguish two sets of cases: (1) those in which traction is being exerted by one or more definite bands; (2) those in which the whole vitreous is diffusely fibrous and by its shrinkage is dragging the retina in. In the former group successful results have been

obtained by the division of the band, and such a procedure is certainly well worth trying. In the latter group it would seem that no treatment ever could be successful or should be attempted.

When the retina is floated in by fluid vitreous passing through a hole in the retina to the inter-retinal space, there is considerable variation in professional views as to the treatment to be adopted.

Holes in the retina are of course often seen but they can be found much more frequently than many believe who are not in the habit of searching for them, and they probably occur a good deal more often than they are found even by those who do look for them. That they are present in every case of detachment as some assert, is a view which I think is untenable on many grounds, but chiefly on the study of the variation in the nature of the fluid or semi-solid exudate in the inter-retinal space.

There are many varieties of holes and they may be caused in several different ways. The macular holes due to trauma or degenerative changes are seldom associated with detachment or, if this does occur, it is slight and as a rule non-progressive. The peripheral holes—large rents, or heretofore shaped slits—are generally associated with extensive detachment, either globular billowy or shelving. Holes in the retina are of considerable importance in their bearing both on diagnosis and also on treatment. As regards diagnosis, it may be parenthetically noted that the presence of a hole excludes I believe the presence of a growth, so far as I have been able to learn or observe, a growth and a hole never have been found to exist together.

As regards treatment, the committee appointed by the Ophthalmological Society of the United Kingdom to report on the results of treatment of detachment of the retina during the war recorded no case of cure by surgical treatment or detachment associated with a hole, and only very rare instances by rest. Such results are borne out by my own experience and that of my colleagues, so far as I have been able to learn.

It would seem then that treatment such as is at present devised in cases of detachment with holes is practically valueless and should not be urged except in only eyes as a last clutch at a straw of hope. If this view be correct it emphasizes the importance of a careful search for holes in every case of simple detachment, so that our patient may not be subjected to a useless form of treatment.

Next we come to the exudative cases where the retina is pushed in by albuminous fluid poured out into the inter-retinal space. It is in this group where the detachment is associated with retinitis and choroiditis, that the greatest hope of success lies. Here by treatment, we may hope to allay any inflammatory process which is taking place to help in the absorption of exudate or by operative measures drain the inter-retinal space.

In theory with the clearly cut groups our course would appear fairly simple, but in practice, alas! the majority of cases cannot be thus pigeon-holed, we are unable to state definitely whether the retina is pushed in or pulled in or floated in, we find no definite signs or signs which we discover no vitreous bands or retinitis striata, we see no sign of inflammation either of the retina or choroid after careful searching, we detect no actual rent. We may thus have no clue as to the mechanism which has produced the detachment. This group includes the bulk of the traumatic and myopic cases. What are we to do with them? It seems only rational till our knowledge improves to give the patient the benefit of the doubt and to treat them.

In whatever group the case falls, should we decide to give treatment let me urge the advisability of treating as thoroughly as is possible once and for all. In our patient let us give him time and incur the tuition and expense of a course of this treatment, let everything known to be useful be tried fully in the six or eight weeks which he is going to devote to the cure, let us give him the satisfaction of knowing that every effort is being made and what is just as important to protect him from the poisoned darts of mere talk or a half-hearted because some one measure—such as puncture or diathermy or uncomplicated operation—has not been tried, may suggest that when the time has been used and that the treatment was valueless.

## DETACHMENT OF THE RETINA.

THE BRITISH  
MEDICAL JOURNAL

Personally I am in favour of attacking the condition from every possible point of view. Absolute rest in bed, constitutional treatment to combat any general condition, absorptive treatment, and counter-irritation to endeavour to remove the exudate in the inter-retinal space—for example, hot-in baths, mercury injections, potassium iodide, blisters to the temple, and subconjunctival injections. If after a fortnight there is no improvement it is advisable to proceed to scleral punctures to drain the inter-retinal space, with or without making an adhesive spot to which the retina may become glued.

For purposes of discussion, I would summarize my remarks in retinitis striata and diffuse fibrous degeneration of the vitreous all treatment is useless.

In detachment associated with a hole treatment offers little chance of success.

Definite fibrous bands in the vitreous may be divided. Detachment associated with retinitis or chorioiditis should be actively treated.

Simple detachment in which the mechanism of the detachment is not determinable should be given the benefit of the doubt and treated.

Firstly, treatment, if attempted at all, should be thorough. The plea of this short communication is for greater thoroughness in our examination of cases of detachment, which should include the careful exploration of the vitreous with the slit-lamp by an expert. By such an examination we may hope to gain new information (1) by which to group our cases more rationally, and (2) by which to treatment may be more successful than that of the past. By these means the more hopeful cases will have the best chance of restoration of sight, and the hopeless cases may be protected from a course of mental strain and expense the disappointing results of which were a foregone conclusion.

## DISCUSSION

Dr W. CLARK SOUTH (Aberdeen) gave short notes of six cases of spontaneous reattachment of detached retina—two traumatic, two idiopathic, one myopic, and one of retina had apparently disappeared, leaving chorioiditis. He discussed the pathological findings in published cases where reattached retina had come to the microscope, special mention being made of the cases of Rounie and Klungström. In one of his retinitis striata cases, an idiopathic one, watched over seventeen years, the long white band at the edge of the reattached area was crossed by vessels which were obviously not retinal, and not likely to be chorioiditis but rather like new vessels, making a strong resemblance to, and in the author's opinion a possible explanation of, those cases described by Sir William Liston in the *Ophthalmic Review* for 1903, under the heading "Angioid streaks of the retina."

Mr INGLIS POLLOCK (Glasgow) said he had operated on two patients with detached retina, both of whom recovered. In the first case a relapse occurred and, although the patient had to wait six months for readmission to the infirmary, a second operation was successful in restoring the retina to its normal situation. This was seven years ago, since when there had been no recurrence. In the second case one operation sufficed and the patient had had no recurrence since the operation, six months ago. Both cases showed that there was no improvement until the inter-retinal fluid was withdrawn, in fact, both patients became worse while they lay up at home with both eyes bandaged. The first showed that success might follow operation further and that he had seen a small detachment cured by operation followed by recurrence of the detachment, and subsequent complete loss of sight in the eye by the extension of the detachment all over the fundus.

Mr J. W. TUDOR THOMAS (Cardiff) described a case of double detachment of the retina in which reattachment of the retina followed in one eye, leaving pigmentary changes

resembling slightly the pigmentation of retinitis pigmentosa. A detachment developed first in the left eye, which became blind, and the lens gradually grew opaque. A large fluid detachment of the retina developed in the right eye about six months after the left eye commenced to fail. Posterior sclerotomy was performed, using the electric cautery. Some opacity developed about the posterior pole of the lens, but ten months later no detachment of the retina could be found, and the retina showed numerous spots of pigmentation. The opacity at the posterior pole had not advanced further up to the time of the last examination. During the last year or so he had observed three cases of detachment of the retina in pregnancy. These cases had several points in common. They were all double detachments, and all three patients had albuminuric retinitis of pregnancy. The detachments all cleared up, and useful vision was restored in each. The vision in one case became 6/12 for each eye, slight macular changes were present.

Dr J. ROWAN (Glasgow) mentioned several cases of retinal detachment, in one of which the condition was obviously due to a tumour, the patient was myopic in the eye affected. Later the myopia was gradually reduced till the patient became hypermetropic. Both conditions were confirmed by retinoscopy. Enucleation was refused till the eye became glaucomatous, it was then removed and the diagnosis was confirmed. He discussed another case where, with rest in bed and subconjunctival injections, there was a complete cure. The late Mr Edward Nettleship had agreed that the detachment was completely back in its place, this lasted for a few months, but after going a short railway journey the condition returned. In spite of different methods of treatment the outlook in these cases was very black.

Dr KERRY (Montreal) gave details of a case of traumatic detachment of two weeks' duration which recovered after a course of iodine injections, in this case there was also almost complete recovery of the lost field. He advocated these iodine injections to promote absorption, and cited another case in which recovery had followed then use. Dr Kerry thought that the subject of retinal detachment would be much better understood when more was known of the cellular function of absorption.

THE VALUE OF ANTISEPTICS IN MODERN  
OPHTHALMIC SURGERY

BY  
SIR ARNOLD LAWSON, K.B.E., F.R.C.S.,  
Ophthalmic Surgeon and Lecturer in Ophthalmic Surgery,  
Middlesex Hospital.

I HAVE been tempted to bring this subject of antiseptics in ophthalmic surgery before the meeting, because it seems to me that there is still a considerable amount of difference of opinion on what is or should be a simple matter in these enlightened days.

Some time ago I read in one of our chief ophthalmic journals a long record of an operation for the extraction of cataract, the description of the operation being preceded by meticulous details of preliminary disinfection and treatment applied to the eye in order to obtain an aseptic condition, which would eliminate risks of operative and post-operative sepsis.

Similarly, a very recent article in the *Lancet* (Ophthalmological) dealing with the same subject of disinfection of the conjunctival sac, starts thus: "It is hitherto proved impossible to make the conjunctiva reliably sterile. It is therefore always with a certain feeling of insecurity that the ophthalmic surgeon proceeds to his operations."

Many surgeons, in fact, seem still to be of opinion that the field of intra-ocular operations requires a somewhat similar course of preparation as is essential when a skin surface is involved. They are impressed with the possibility

\* A paper read before the Section of Ophthalmology at the Annual Meeting of the British Medical Association at Edinburgh, 1927.

of disaster in the way of sepsis if such preparations are not carefully observed.

I propose to consider the question of treating the ophthalmic operation field, antiseptically or aseptically, from four points of view (1) contamination from the conjunctiva (2) contamination from instruments and dressings, (3) contamination from the fingers of surgeons and assistants, and (4) contamination from the air.

There are, of course, other minor sources of contamination but the ones just mentioned are the most important, and I will confine my remarks to them.

#### The Conjunctival Sac

Many years ago I published the report of an exhaustive inquiry into the bacteriology of the normal conjunctival sac. The results of this investigation which so far as I am aware, have never been contradicted, and which have certainly guided me safely through many years of operative work, may be summarized as follows. The normal sac is in itself antiseptic and requires no treatment prior to operation. So far as its lower section is concerned it is never sterile, it always contains many organisms but these are either in themselves perfectly harmless, or if not so harmless, their virulence is speedily destroyed by some inherent antiseptic power of the conjunctiva, which in this respect resembles the peritoneum. This can be easily proved by growing cultures from the lower sac and injecting a solution into the conjunctival sac of animals or even subconjunctivally. In neither case does anything happen. The normal conjunctival sac can never be sterilized for even twenty-four hours by any known means, and all attempts to effect this by antiseptic lotions of sufficient strength to be as effective germicides are futile simply tending to defeat their object by setting up a reactionary irritation.

Long before antiseptic or the later aseptic surgery was introduced intra-ocular operations were performed with comparative safety as compared with operations on the body. Indeed long after the principles of aseptic surgery were generally accepted ophthalmic surgeons as a class took no very special precautions. I was the first surgeon at Moorfields Hospital to adopt an overall and my election was in 1890, my revered teacher Sir John Tweedy up to the time of his retirement in that year always used his index finger to effect counter-pressure, and to prevent the eye rotating inwards when making his catract section instead of employing fixation forceps. The result obtained then will bear quite a favourable comparison with those seen nowadays with masks, caps, overalls and all the other appurtenances, which are quite rightly held to be desirable. I do not advocate a neglect or precautionary measures before operation the point I wish to make is that the routine use of antiseptic measures arises from a wrong appreciation of facts. What we have to ensure is not that the conjunctiva is sterile for that is unnecessary and impossible, but that it is healthy, and we can do that by the simplest means. The one great factor in determining this point is the presence of discharge which can be definitely proved by tying up the eye for a few hours with an aseptic pad. If any discharge appears on the pad on removal or is found clinging to the lashes or eyelids then the conjunctiva is unhealthy and means must be taken to free the sac from the cause of the discharge before operation is undertaken. Taking smears from the conjunctiva and acting on the report of the presence of organisms found by this method of examination, is only of value if discharge is present in its absence the organisms found may be held to be avirulent and harmless. As a matter of fact it is generally possible to tell by mere inspection whether the conjunctiva is healthy or not but I always adopt this well known and simple expedient or determining it.

If the conjunctiva at the time of operation is healthy it may safely be assumed that it will remain healthy during post operative treatment under bandage and pad, and such is indeed the case.

#### Contamination by Instruments and Dressings

This may be dismissed in a cursory manner, for it is a first principle of all surgery that instruments and dressings

must be sterile. I would simply just mention the point that the instruments should not only be sterile but dry.

#### Contamination from Surgeons' and Assistants' Fingers

The surgeon's fingers as a source of contamination may obviously be a fruitful cause of disaster. Some surgeons avoid trouble by wearing rubber or other forms of gloves but, personally speaking I found the disadvantages or gloves in destroying as they do, the fine sense of touch which is so important in many ophthalmic operations to outweigh entirely their manifold advantages in maintaining aseptically, and I entirely gave up their use many years ago in intra-ocular and strabismus operations. But if no gloves are used the surgeon must be meticulously careful that no part of any instrument other than the point or handle is ever touched by his fingers. It has to be remembered that washing and scrubbing the hands before operation in no sense renders the fingers sterile. It has been shown that rubbings taken from fingers freshly washed and scrubbed in warm water produce luxuriant growths of organisms and that while removing surface contamination to some extent, the hands still remain a means of readily infecting the wound. Personally, I endeavor to counter the point to some extent by well soaping my hands in spirit after scrubbing, and by having a bowl of spirit at hand during operation in which I can rinse my hands at any moment if I think it desirable. I do not think this simple act is nearly so much appreciated as it ought to be otherwise one would not observe as I have often done great indifference on the part of surgeons in the handling of instruments when gloves are not worn. I have often seen surgeons, when operating for strabismus, pick up needles with their fingers and put the needles in the needle holder, instead of using serrated forceps for the purpose with the consequence that the sutures are apt speedily to become more or less septic. Then, again sutures are themselves a ready means of contamination, even after careful sterilization. The satisfactory manipulation of sutures presents real difficulties and requires meticulous care. It is presumed that in cases where sutures are going to be employed the skin of the face as a matter of course will be shut off by a gauze mask excluding all except the operation field while the scalp is guarded by a folded sterile cloth. The sutures must be kept free from the surgeon's finger, and this can only be effected by the greatest attention to detail. If, as is commonly the case the needles and threads are rolled each one on a piece of folded gauze or lint the needle should be disengaged from the roll with serrated forceps as just mentioned and the suture as it is unrolled should be held by the assistant in a pair of serrated forceps, and kept free from all contact with his or the surgeon's hands until the suture has been properly adjusted, and when it is being tied the surgeon must be extremely careful that his fingers never approach that part of the suture which is applied to the wound area. It is all perfectly simple but often I think, there is lacking that degree of attention to detail which is required.

It must be admitted that even with the greatest attention to detail sutures will sometimes touch something that they should not and in this respect an efficient antiseptic which can without any irritation whatever be applied to the wound area is most helpful, and gives the surgeon a great feeling of security.

There is nothing I think so good for this purpose as flamine. A solution of 1 in 1000 of this drug can be freely applied to the eye at the time of applying the sutures and thereafter it can safely be dropped into the eye twice daily in a strength of 1 in 4000 without causing the slightest disturbance or without producing the least delay in the healing process. The charge has been made against flamine that it delays healing but I can assure all who have not tried it that this accusation when flamine is used of the strength just mentioned (1 in 4000), is entirely baseless. Healing pursuing its natural course by first intention. I can assure you using this drug regularly, as I have done now for ten years I have not had a single case of infected sutures after strabismus operations.

*Contamination from the Lash Area*

The last point I wish to mention is contamination from the lash area, which is the neighbourhood most difficult to preserve clean when in eye has to be kept bandaged for any length of time. It is not, I am thankful to say, the most important, because there is not the same risk of infection of the operation field from the ciliary border as there is from the other sources of contamination—the conjunctiva, the instruments and accessories, and the surgeon's fingers. On the other hand, I think it is quite impossible, unless special means are taken, to keep the lash area from becoming dirty, and often very quickly so when the eye is kept tied up. In other words, it is quite impossible to sterilize the ciliary borders satisfactorily on account of the organisms which lie beneath the surface round and about the lash follicles. The testing pad worn before operation may be entirely free from all discharge, and the lashes themselves be apparently perfectly clean, but soon after operation, even if they have been cut short, as they should have been, the stumps are apt to get sticky and dirty, and the discharge will then tend to get more and more objectionable, unless the source of trouble can be checked.

It is, therefore, in this regard, as well as in the dealing with sutures, that a non-irritating, efficient antiseptic becomes of extreme value, and once more I urge the use of fluvine, which will generally do its work admirably.

After every operation I cover the affected eye with a gauze pad well sprinkled with a 1 in 4,000 solution of fluvine. It makes a delightfully comfortable dressing, which I change twice daily, if this procedure is followed the lash area will rarely cause any trouble whatever. If trouble does occur it will be of a mild character and easily controlled. Something must then be used in addition to, or as a substitute for, fluvine, and I know of nothing better than a 2 per cent solution of protargol employed

three daily as drops. Used at this strength protargol never irritates the wound, and it acts very efficaciously in arresting the discharge.

To sum up, then, the gist of these few remarks is to urge that the maintenance of a healthy operation field with quick normal healing can be obtained by the simplest methods before, during, and after operation. Antiseptics of any kind are only needed as extra measures, especially with regard to needles, sutures, and the lash area. If to these simple measures is added meticulous attention to detail, suppuration in the operation field can be eliminated with absolute certainty.

One exception must, however, be made to this assertion, and that arises when force of circumstances prevents the taking of routine precautions. It is occasionally necessary to operate on an acute glaucoma when there is intense congestion and obvious sepsis. In such an exceptional case I think the best antiseptic to use is hydrogen peroxide, with which the eye is flooded immediately before the knife section is made. It is much better than fluvine, because the latter is strictly an antiseptic in the true sense of the word, and is not of much value when sepsis is already present.

Finally it is, perhaps, legitimate to quote personal experience in these matters, and I can claim that, in my private practice, I have never experienced the tragedy of intra-ocular suppuration after operation. In hospital practice I must, I think, have occasionally experienced this misfortune, though I cannot recall any instances, and certainly I have no single case impressed on my mind. In hospital work, however, it is not nearly so easy, for many reasons, to impress attention on certain details or to see that such details are carried through, and consequently accidents are more likely to occur there than in private work, where one assumes sole and entire responsibility.

## **PATHOLOGY OF THE TUBERCULOSIS OF CHILDHOOD AND ITS BEARING ON CLINICAL WORK**

BY

EUGENE L. OPIE, M.D.

(From the Henry Phipps Institute, University of Pennsylvania, Philadelphia.)

Recognition of the widespread occurrence of tuberculous infection acquired during childhood introduces into study of the disease two conflicting factors, one or other of which is often forgotten: (1) the increased resistance to the disease from a somewhat ineffective immunization, and (2) the danger that latent infection may cause manifest and perhaps fatal disease.

Attention is limited to tuberculous infection which is so advanced that it produces cough, fever, loss of weight, and obvious physical signs, while less advanced infection which remains concealed, for a time at least, is ignored, spread of the disease in families and in the community is studied under a heavy handicap, and ancient problems concerning its contagion remain unsolved. We might with equal reason study the epidemiology of measles by limiting our attention to instances of the disease followed by pneumonia, or of small-pox by excluding all cases except those with hemorrhagic lesions.

*The Pathology of Latent Tuberculosis*

I am inclined to believe that more knowledge of the pathology of tuberculosis can be obtained by careful examination of the tuberculous lesions of those who die from causes other than tuberculosis than from fatal instances of the disease. The frequency of concealed tuberculous infection is thoroughly recognized, in great part as the result of almost innumerable studies made with the tuberculin test, but the variety and severity of latent tuberculous lesions is not fully understood. Sir Arthur Newsholme<sup>1</sup>

assembled evidence to show that there is a long latent period between exposure to infection and the appearance of the symptoms of phthisis. The frequency of calcified pulmonary nodules which may be regarded as scars of an infection required in childhood is well known, but it is less fully realized that one in five of adults who die from causes other than tuberculosis have apical tuberculous lesions which are caseous or partly calcified.

X-ray photographs of lungs excised at autopsy furnish a satisfactory means of depicting the distribution of tuberculous lesions, particularly when calcium salts have been deposited in caseous material, or new formation of fibrous tissue has increased the density of lung tissue. They serve as a guide in dissection to scattered nodules and reveal lesions which would otherwise be difficult.

All types of lesions which x-ray plates prepared from excised lungs can be identified in plates prepared from the living chest. Radiologists who are doubtful concerning the interpretation of latent tuberculous lesions evident in x-ray plates of the living chest should prepare a series of plates from lungs removed at autopsy and should identify by dissection the lesions which are revealed.

*First Infection with Tuberculosis*

Tuberculosis of infancy and early childhood, which resembles that of an animal inoculated with tubercle bacilli, forms a lesion at the site of infection and quickly affects the nearest lymph nodes. The severity of tuberculosis in early infancy seems to indicate great susceptibility to the disease, but exposure of the infant to massive infection from those who tend it may explain the high mortality from tuberculosis during the first year of life. At this period general dissemination through the body accompanied by tuberculous meningitis is common. During the second year of life the mortality from tuberculosis falls rapidly, and during the next few years gradually. From the fifth to the twelfth year the death rate is lower than at any other period. It is noteworthy that during this interval of low mortality infection with tuberculosis, indicated by the tuberculin reaction, makes its appearance with

<sup>1</sup> A paper read in giving a discussion in the Section of Tuberculosis at the Annual Meeting of the British Medical Association, Edinburgh, 1927.

great frequency, but the lesions with few exceptions heal. A nodule is formed in the lung substance, and fact which are usually much larger are formed in the nearest lymph nodes. Occasionally, particularly when disease of bronchial lymph nodes is advanced, a few tubercles which undergo encapsulation are formed in distant organs such as spleen and liver,<sup>2</sup> but general dissemination and death are uncommon. With healing, encapsulation is followed by calcification, and scars of these first infections remain throughout adult life in lungs, bronchial lymph nodes, and sometimes in other organs.

Tuberculosis in young children usually proceeds more rapidly in the lymph nodes than in the lung parenchyma, so that the lesion or bronchial lymph nodes at the hilum of the lung is often very conspicuous. Many have thought that the disease begins in the lymph nodes and spreads peripherally into the lung substance. A nodule occasionally found with difficulty is, as Kuss<sup>3</sup> showed, invariably present in the lung substance and is presumably the primary site of lodgment of tubercle bacilli which have entered by way of the bronchi. The term "hilum tuberculosis" is, it seems to me, unfortunately chosen, because it suggests that the disease has its origin at the root of the lung. In x-ray plates made during the progress of pulmonary tuberculosis in children the lesion occasionally seems to extend from the hilum to the periphery of the lung, but this deceptive appearance is caused

FIG 1.

FIG 2.

FIG 1.—Diagram showing tuberculosis of the lungs and tracheo-bronchial lymph nodes with secondary extension into adjacent lung substance in a child aged 1 year. The primary focus (a) which contained a small cavity was in the right lower lobe. The caecus tuberculous centre of a lymph node had penetrated the capsule (b) and produced a secondary infection of the adjacent right upper lobe. Death occurred with tuberculosis widely disseminated throughout the body.

FIG 2.—Diagram showing tuberculosis of lung (a) and of tracheo-bronchial lymph nodes (b, c) with secondary extension of tubercle from lymph node to lung substance in a girl aged 6. The primary focus of infection was the caecus encapsulated nodule (a) 1.5 x 1.2 cm. The caecus centre of the lymph node (b) had penetrated the capsule and extended into the lung substance. The caecus centre of the large lymphoid mass (c) had penetrated the capsule of the node and the adjacent tracheal wall so that caecus material protruded into the lumen of the trachea just above the orifice of the right bronchus. There were tuberculous ulcers of the intestine, tuberculous peritonitis and tuberculous salpingitis.

by the projection of three dimensions on one plane. Post-mortem examination occasionally shows that caseous lesions of bronchial lymph nodes have penetrated the capsule of the node and produced tuberculous pneumonia of the adjacent lung (Fig 1) or have ulcerated through the wall of a bronchus (Fig 2) and perhaps caused dissemination of the disease in the domain of tributary bronchial trunks but in such instances a primary focus of infection can be found in the peripheral lung field (Fig 1 a Fig 2 a).

Experimental studies indicate that tuberculosis is conveyed to susceptible animals with much more difficulty by way of the gastro-intestinal tract than by way of the lungs. Several years ago I had the opportunity to compare the frequency of latent tuberculosis of mesenteric lymph nodes in British and American adults.<sup>4</sup> In slightly more than one-fourth of young British adults examined who had died from causes other than tuberculosis there were healed or healing tuberculous lesions of the mesenteric lymph nodes whereas in Montreal Klotz<sup>5</sup> found obsolete lesions in 8 per cent of those examined and in San Francisco Ophuls found them in 5 per cent. I found that focal lesions of the lung were usually absent when mesenteric tuberculosis had occurred. Todd<sup>6</sup> has recently found that the incidence of mesenteric tuberculosis is very high in young persons in Edinburgh, and has observed that pulmonary lesions are uncommon when mesenteric lesions are numerous.

### Reinfection with Tuberculosis

Phthisis of adults, unlike the first infection of childhood has little resemblance to tuberculosis of susceptible animals,<sup>7</sup> but resembles the disease of reinfecting animals. Why select the apex of the lung is not yet evident, but once established it tends to pursue a chronic course and remains so in the last stages, a localized disease of the lung. The apical lesions which heal so completely that they never produce symptoms are much more numerous than those which cause progressive disease. Less than 1 in 10 of all deaths is caused by tuberculosis, whereas approximately 1 in 5 of those who die from causes other than tuberculosis have characteristic tuberculous caseous or calcified lesions of the pulmonary apex. The number of those having fibrous apical scars with no gross microscopic characters of tuberculosis is even greater.

Once infected, the experimental animal undergoes change, which alter its reaction to the bacteria and bacterial products (tuberculin). We have no clear understanding of the relation between hypersusceptibility in the infected animal and the resistance conferred upon it by immunization but analogy with similar changes produced by more readily studied protein substances<sup>8</sup> suggests that accentuation of the inflammatory reaction following infection by the tubercle bacillus is a beneficial process which tends to overcome the second invasion.

This conception concerning the pathogenesis of phthisis has little value unless it is in harmony with changes which are evident in the human body. (1) When phthisis of adults occurs the calcified scars of a first infection can be found in the lung substance and in adjacent bronchial lymph nodes.<sup>9</sup> (2) Like a second infection of experimental animals, phthisis of adults pursues a chronic course, remains localized and does not implicate the nearest lymphatic nodes. (3) When people who have not come into contact with European civilization escape tuberculosis during childhood they suffer if infected during adult life, with a type of tuberculosis which resembles that of childhood. The susceptibility to acute forms of tuberculosis of native African troops serving in Europe has been clearly shown by Dr Lyle Cummins.<sup>10</sup> The American negro not infrequently escapes infection during childhood and exhibits recently fatal lesions of first infection during adult life. (4) When reinfection occurs at an early age, after a still earlier first infection it exhibits the characters of the disease of adults. The adult type of tuberculosis with localization in the apex, chronic course, and cavity formation is seldom seen during the first decade of life but during the second decade with increasing frequency as age advances. In adolescent children after 15 years of age pulmonary tuberculosis is in most instances has the characters of the adult disease.

There are two peaks upon the curve representing mortality from tuberculosis. There is one in infancy reaching a maximum during the first year of life. It is due to first infection having its origin in the lungs and bronchial lymph nodes or, in a smaller number of cases in the intestine and mesenteric lymph nodes. Mortality from these lesions of first infection diminishes rapidly during the second year and then gradually during subsequent years until the fifth year. After the fifth year and during the greater part of childhood mortality is lower than at any other period of life. After the twelfth year in girls and somewhat later in boys the curve of mortality begins to rise and reaches a second peak in early adult life or even later. It is noteworthy that this second wave of mortality from tuberculosis is caused by lesions of reinfection having their origin with a few exceptions in the apices of the lungs.

### Bacteriology of Latent Tuberculous Lesions

My associate Dr Aronson<sup>11</sup> and I have attempted to determine the frequency with which living tubercle bacilli can be recovered from latent lesions or first infection present as encapsulated and calcified nodules in the lungs and bronchial lymph nodes. Tubercle bacilli are seldom recovered from these healing nodules unless there is a latent apical lesion in the same lung and when latent apical lesions are present living tubercle bacilli are

recovered not only when material from enlarged nodules is injected into guinea-pigs, but when material from parts of the lung which contain no evidence of tuberculosis is used for inoculation. These observations indicate that living tubercle bacilli are present in the surrounding lung tissue rather than in the nodule itself. In latent lesions of the apex, on the contrary, tubercle bacilli are almost invariably found when the lesion is fibroid and caseous, and persist even after apparent healing, so that they are found in one-fourth of the fibrous apical scars which have none of the gross or microscopic characters of tuberculosis. Tubercle bacilli in most, if not all, instances seem to have disappeared from the lesion of childhood by the time the lesion of reinfection makes its appearance. Furthermore, histological evidence furnishes little support to the opinion that the apical lesion of adults is derived by extension from the focal lesions of childhood, for the one is seldom in continuity with the other, and not infrequently the lesion of first infection is in one lung, whereas the apical lesion of reinfection is in the opposite organ. The available evidence

physician. The means at our disposal for the discovery of latent tuberculosis are the tuberculin test, which shows whether tubercle bacilli have found lodgement in some part of the body, and x-ray examination, which, within certain limitations, discloses the character and extent of the lesion. The term "latent," in the sense in which I have used it, has long been used in medical literature, and may be found in the writings of Lenné and Louis. Some authors have assumed that it is applicable only to lesions which are dormant or arrested, but long accepted usage gives no support to this interpretation of the word. Lesions which are unaccompanied by symptoms or physical signs are often progressive, and manifest disease is invariably preceded by a long or short period of latency.

My associate Dr. McPhedrin and I have undertaken a study of latent tuberculous lesions in children of families exposed to tuberculosis, and have attempted to determine whether they produce manifest disease. By means of x-ray examination we found that it was possible to discover all types of lesions which can be recognized in x-ray plates

FIG. 3.—Graphic chart used to depict the occurrence of latent and clinically manifest tuberculosis in families. Vertical lines represent each member of the family, and their length corresponds with the duration in years of residence within the household. They are divided upon a horizontal line which represents the date at which the family came under observation. Later observations are recorded below this line. Tuberculin reactions are shown by 0 (negative) or from one to three plus signs over the quantity in milligrams (0.01 to 1) of tuberculin used. The result of sputum examination (sp) is indicated by zero or plus placed above the number of examinations.

FIG. 4.—Diagrams prepared from x-ray films to show the position of the lesion in the lungs of children of the family shown in Fig. 3.

of excised lungs and identified by subsequent dissection. Examination of members of families exposed to contact with tuberculosis showed that latent lesions were more numerous and more extensive among them than in families which had no contact with the disease. The severity of infection bore a measurable relation to the elimination of tubercle bacilli by the tuberculous member of the family, and to the duration of exposure to contact with the micro-organism. Transitional stages from latent to manifest disease occurred, and it became evident that it is often possible within certain limitations to predict clinically manifest disease long before it makes its appearance.

These observations have brought about important changes in our procedures for the prophylactic treatment of tuberculosis. Families are studied as units and the progress of infection in them determined. The usual method of sputum examination is the best means for determining whether members of a family are exposed to present danger of contagion but latent infection in members of a family may serve as an index of past exposure to open tuberculosis. We have prepared for each family under the care of our out-patient department a graphic chart (Fig. 3) which records how long each member of the household has been exposed to contact with tuberculosis, and shows for each the presence or absence of a tuberculin reaction, the character of any latent tuberculous lesions revealed by x-ray examination (Fig. 4), and the presence or absence

indicates that pulmonary tuberculosis of adults is not the continuation of an infection acquired in childhood, but is an exogenous reinfection.

#### Clinical Significance of Latent Tuberculosis

Concealed foci of tuberculosis in lungs and lymph nodes which give none of the manifestations of pulmonary disease may be the source of serious tuberculosis in distant organs. Ophuls<sup>13</sup> has recently attempted to determine the primary focus of infection when tuberculosis causes recognizable disease of the genito-urinary tract, adrenals, bones, joints, etc. In seven cases of Addison's disease tuberculosis of the adrenal had apparently had its origin in a pulmonary focus, and in six instances this focus had healed. In twenty-seven cases of tuberculosis of bones and joints the primary focus of infection was in the lungs, and in one-third of these it was healed. Genito-urinary tuberculosis is always secondary to tuberculosis of lung or intestinal tract, and in 20 per cent of instances referable to the lung the pulmonary lesion was healed.

Latent tuberculosis may be defined as tuberculous infection which is unaccompanied by significant symptoms evident to the patient or by physical signs discovered by the

of manifest disease which has been recognized by symptoms and physical signs

The children of the family shown in the chart (11-3) were exposed to tuberculosis of the father and of the mother. Sputum of habits were when first seen had in them a tubercle bacillus and a small nodule in the lung. Two years later a focus of fibrin in the left lung and riles were heard over it. Another had advanced tracheo-bronchial tuberculosis. Anna when first seen had nodules in the lungs and a latent apical lesion on the right side. One year later there were bilateral apical lesions. After another year the lesions had extended and riles were heard over the apex.

This study has emphasized the value of the tuberculin reaction as a means of recognizing tuberculosis in children. Its significance is well known diminishes with increasing age from infancy to adult life when immunization of large cities almost all react. In our group of families exposed to open tuberculosis over 80 per cent have acquired an active tuberculin reaction before the age of 5 years and 90 per cent at the age of 10 whereas 23 per cent react at the age of 5 and 62 per cent between the ages of 15 and 20 years.

Examination by x rays gives trustworthy evidence concerning the frequency of latent tuberculosis among children exposed to contact with open tuberculosis and furnishes a means by which the severity of infection may be measured. Focal lesions within the lung substance are readily recognized if the characters of the lesions found at autopsy are kept in mind. Blood vessels directed in the axis of the calcified nodules. Thirty per cent of our children who were exposed to tuberculosis in their families had pulmonary nodules as compared with 17 per cent of the children who were not thus exposed. More significant is the recognition of lesions of the tracheo-bronchial lymph nodes, although anatomical study (Fig. 5 from the lungs of a youth who had been in contact with open tuberculosis) shows that they invariably accompany focal pulmonary lesions. They are seldom recognizable in x ray films unless they have attained considerable size. Tuberculosis of tracheo-bronchial lymph nodes was found in 23 per cent of children in contact with open tuberculosis, and in only 4.5 per cent of children of non-contact families. The average duration of contact with open tuberculosis when tuberculosis of tracheo-bronchial lymph nodes is recognized has been four years and five months and the lesion is seldom found in those who have been exposed during a period of less than two years.

Of greater import is the occurrence of latent apical tuberculosis in adolescent children. At the time of our report one year ago this lesion was found in 16 per cent of our children of families with open tuberculosis, but subsequently the incidence has increased to 32 per cent. Latent apical disease has not been found in children of non-contact families. Among those in whom latent apical tuberculosis has made its appearance including adolescent children and adults the average duration of contact has been even years and 11 months but this is evidently no the minimal period of contact required to produce the lesion.

Parallel with the frequent occurrence of such latent lesions of tuberculosis in families with open tuberculosis there is high incidence of clinically manifest tuberculosis with symptoms and physical signs. In the group of contact families 9 per cent of children among those examined

had manifest tuberculosis. No manifest disease has appeared in the non-contact families.

This study has shown that the usual method of sputum examination reported at short intervals is an effective means of measuring the danger to which is infected individual subjects his family. The frequency of tuberculin reactions of lesions recognized by x ray examination and of clinically manifest disease was much lower in families in which a member suffered from pulmonary tuberculosis but had no tubercle bacilli in his sputum than in families exposed to open tuberculosis and was only slightly greater than in those having no contact with the disease. There was another group of families in which some members had symptoms and other evidence suggesting tuberculosis. In these families with suspected tuberculosis the incidence of infection was not materially greater than in non-contact families.

Isolated nodules recognized in the peripheral lung field in most instances represent well circumscribed infections and have little clinical significance. Although they indicate that tuberculous infection has occurred and his doubtless conferred some degree of immunity upon the child they do not exclude the possibility of progressive disease or of reinfection.

FIG. 5.—Reproduction of an x ray film prepared from the lung removed at necropsy of a youth (19 years) who died with purpura fulminans and an enlarged tracheo-bronchial lymph node. The diameter of the area of necrosis (Fig. 5) is 1.5 cm. (the figure) and there were 1.5 cm. of the right lung (referred to in the text) at the hilum of the lung. A right lymph node containing calcified tubercle bacilli was lymphoid in character and placed in the bifurcation of the trachea. The calcified material (Fig. 5) was partly calcified and encysted and it was partly calcified.

with few exceptions are recognizable only when calcification has been deposited within the caseous material. It has been claimed that the lesions of bronchial lymph nodes are never visible except when they are calcified and completely healed and no longer a source of danger. This view is certainly incorrect. When there is impregnation with calcium salts scarcely sufficient to increase the consistency of caseous material, a lesion which is arrested and calcified in one part may be progressive in another. Figure 6 represents the lung of a child there are in one part nodules of lungs and in another part progressive caseous lesion (c d) which have produced death by general dissemination. It is probable that the two kinds of lesions since they occur in a child 12 years of age began at approximately the same time. Figure 7 represents the lungs of a child 9 months of age with caseous and calcified foci in the lungs and bronchial lymph nodes. Death occurred with disseminated tuberculosis and tuberculous meningitis.

Although I believe that recognizable lesions of the tracheo-bronchial lymph nodes in many cases indicate disturbance of the local and local complications that they should be regarded with grave concern especially when they appear during the first decade of the beginning of the second decade of life. This opinion is

### Tuberculosis of Tracheo-bronchial Lymph Nodes

Tuberculosis of the tracheo-bronchial lymph nodes is recognized by clearly defined oval granular shadows in contact with the larger bronchial trunks at the hilum of the lung or in immediate contact with the trachea and often below the bifurcation (Fig. 4). Accentuation of the hilum shadow or thickening of the mediastinum is seldom due to tuberculosis of lymph nodes and does not aid in the recognition of the disease. Lesions of the tracheo-bronchial lymph nodes often attain considerable size and in such instances indicate that infection is advanced. Occasionally very large groups of caseous lymph nodes are well defined in x ray plates, in comparison with x ray films prepared from lung removed at autopsy shows that tuberculous lesion of lymph nodes

MEDICAL JOURNAL

based upon the frequent coexistence of tuberculosis of the tracheo-bronchial lymph nodes and clinically manifest lesions of the lungs in children of families exposed to open tuberculosis, and the development of manifest tuberculosis in another group of children in whom tuberculosis of the tracheo-bronchial lymph nodes has been recognized. All of our children who exhibit this lesion have been placed

signs are at times astonishing. The anatomical characters of apical lesions depicted in x-ray plates when associated with clinical evidence of the disease do not differ from lesions with which there have been slightly elevated tempera-

FIG 7

FIG 9

FIG 10

FIG 6.—Diagram of lungs with caseous calcified lymph nodes in one lung (b) and with progressive caseous lesions in the other (c, d) in a child 2 years of age. In the left lung there were two small caseous encapsulated nodules at the hilum of the lung, nearby there was a lymph node replaced in great part by a tuberculous lesion with caseous partly calcified centre and fibrous capsule. In the right upper lobe below the pleura there was a wedge-shaped area of consolidation, the adjacent lymph nodes were much enlarged and caseous. Death occurred as the result of tuberculous meningitis.

FIG 7.—Diagram showing encapsulated tuberculous foci in lungs and lymph nodes with tuberculous meningitis in a child aged 9 months. At the base of the left lower lobe (posterior view in diagram) there was a caseous encapsulated focus impregnated with caseum so that opaque spots were seen in an x-ray plate of the excised lung, though the caseous material was soft. At the hilum of the lobe there were lymph nodes with lesions of the same character. On the right of the trachea there was a large lymph node replaced in great part by caseous material surrounded by fibrous tissue.

FIG 9.—Diagram showing the distribution of lesions shown in Fig 8 (in which right and left are reversed). FIG 10.—Diagram showing fibrous scar of apex and advanced calcified tuberculous lesions of tracheo-bronchial lymph nodes in a girl aged 13. Death occurred as the result of typhoid fever. At the right apex extending inward from the puckered pleura there was a thick fibrous scar 2.5 cm in length. In the substance of the right upper lobe there was a nodule 0.5 cm in diameter with caseous, partly calcified centre and fibrous capsule. In the lung substance near the hilum of the lobe were two small lymph nodes which contained caseous partly calcified and encapsulated nodules. At the hilum of the lobe was a large lymphoid mass studded with caseous and calcified nodules, and a similar mass was wedged between the inner surface of the right upper lobe and the trachea. The spleen contained encapsulated tubercles from 1 to 2 mm in diameter, with caseous and calcified centres.

so far as possible under conditions which are known to retard the progress of tuberculosis when it is manifested by symptoms and physical signs. Effort is made to avoid malnutrition and fatigue. I feel sure that measures which are effective in retarding the progress of clinically manifest tuberculosis will in most instances prevent the transformation of latent infection into evident disease.

The presence of soft shadows in the peripheral lung fields is recognizable in x-ray plates of the chest is often difficult to interpret, and introduces a consideration of the diagnosis of pulmonary tuberculosis in children. They are at times unrecomplicated by symptoms or physical signs. The following criteria indicate that these soft shadows are the result of tuberculous infiltration: (1) occurrence in a child in contact with tuberculosis, (2) an active tuberculin reaction (with 0.01 mg of old tuberculin), (3) association with lesions of adjacent lymph nodes recognizable in the x-ray plates.

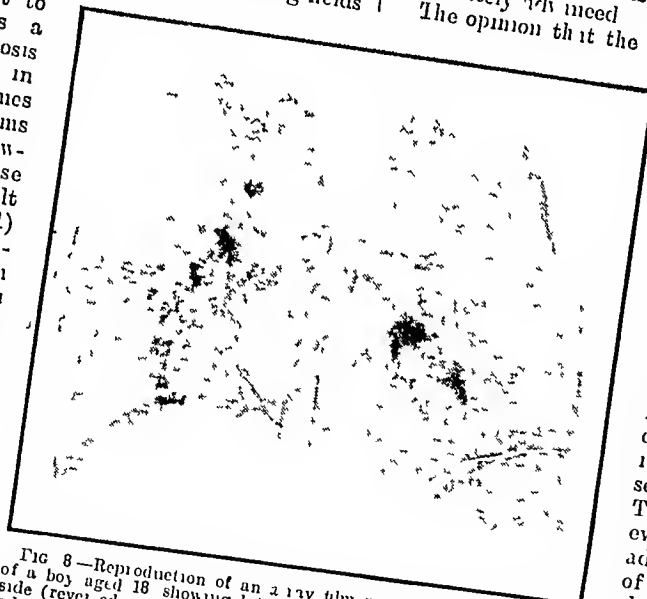

FIG 8.—Reproduction of an x-ray film prepared from the lungs of a boy aged 18 showing latent apical tuberculosis on the right side (reversed in the figure) and calcified nodules in the lung and adjacent lymph nodes on the left side. Death occurred as the result of peritonitis following laparotomy. At the right apex in continuity with the puckered pleura there was fibrous and caseous tissue forming a mass 3 cm across. In the left upper lobe there was a small calcified nodule and larger firmly calcified nodules in lymph nodes at the hilum of the lobe. In the substance of the left lower lobe and in adjacent lymph nodes there were similar lesions.

time, cough, and rales heard over the affected apex. During the relatively short period of our observations—months, from years—we have had opportunities of following the transition from latent apical disease to advanced tuberculosis with loss of weight, cavity formation, and appearance of tubercle bacilli in the sputum. It is noteworthy that adolescent children with latent apical lesions may be well nourished and in good health. Loss of weight does not usually make its appearance until the disease is moderately advanced. The opinion that the tuberculosis of adults has its origin in childhood has long been maintained and is still widely held. Von Behring claimed that all tuberculosis had its origin in early infancy, but most of those who think that phthisis does not originate in adult life believe that it is the continuation of an infection acquired at any time during the period when focal lesions are making their appearance in lungs and bronchial lymph nodes. Nevertheless, it may be noted that few of those who discuss the subject define the relation of these lesions to subsequent apical disease in adults. There is, as I have shown, no evidence that tuberculosis of adult life is the continuation of the first infection of childhood. Nevertheless, it is evident that latent apical tuberculosis of older children may gradually develop into phthisis of early adult life. The transition may be followed by means of radiological examinations.

Latent apical lesions of adolescents which have all of the characters of infection are in a considerable number of instances associated with advanced tuberculous tracheo-bronchial lesions. These massive tracheo-bronchial lesions accompanied by latent apical tuberculosis with few exceptions occur in children who have been exposed to intimate contact with open tuberculosis for several years, and apical

## Latent Apical Tuberculosis of Adolescent Children

Latent apical tuberculosis is encountered with increasing frequency as age increases during the second decade of life, and is evidently in many instances the precursor of phthisis of early adult life. Examination of adolescent children of families in contact with open tuberculosis has revealed almost all of our cases of latent apical disease, but in a few instances it has been discovered in others. It occurs only when contact with open tuberculosis has been long continued. In x-ray plates it is recognizable as a mottled shadow in one or the other apex, evident in the second interspace, and extending into the third and even into the fourth interspace. The extent and density of lesions which are unaccompanied by symptoms and physical

disease is superimposed upon the first infection because resulting immunity is an ineffective protection against tubercle bacilli in vast numbers.

#### Conclusions

Latent tuberculous lesions of the lungs and tracheo-bronchial lymph nodes are revealed by radiological examination and when they are accompanied by an active tuberculous reaction it may be assumed that they are not dormant or healed. These lesions well known to pathologists may have grave clinical significance. They are not infrequently the source of tuberculosis of meninges, bone, genito-urinary system, adrenals and other organs, they may produce clinically recognizable pulmonary tuberculosis of the type of childhood, or, as in index or exposure to tuberculous infection, may be followed by the adult type of pulmonary disease.

Latent tuberculosis of the tracheo-bronchial lymph nodes or young children and latent typical tuberculosis of children during the second decade of life indicate the presence of grave infection and may forewarn against clinically manifest disease. These latent lesions appear with great frequency in families exposed to open tuberculosis. All members of families in contact with tuberculosis should be given repeated tuberculin tests and radiological examinations even though they appear to be in good health. When these examinations reveal grave latent disease the well known measures directed to retard the progress of tuberculosis will prevent the development of manifest disease.

Tuberculous infection in childhood increases resistance to the disease but is at the same time a source of danger. Recognition and control of latent infection are effective means of preventing tuberculosis.

#### DISCUSSION

Dr R. G. CANT (London) said that the question of the primary tuberculous focus in the lung in childhood had not received much attention in this country. He had reported in the *Quarterly Journal of Medicine* (1919) 84 consecutive post-mortem examinations on children under 10, 16 were tuberculous, and of these 10 had shown the primary lung focus. Further experience had convinced him that Guon's theory of the relation of primary focus and glandular infection was tenable. He showed diagrams of the scheme of lymphatic drainage from the lung, and said it was possible to predict from the glands infected in a particular case the position of the primary focus in the lung. He supported this by diagrams of three cases. He believed it could be proved that the mediastinal glands were secondary to the lung focus, since while there was a lung focus there were tuberculous glands in the corresponding mediastinum and where the mediastinal glands were tuberculous a tuberculous focus was present in the lung. Moreover anatomical study had shown those glands to be tuberculous which would be expected to be so affected if the lung focus was primary. The changes in the glands never appeared older than those in the lung focus. He thought it was also proved that the lung focus was not secondary to one elsewhere in the body. In the majority of cases showing a lung infection no focus could be found outside the thorax. In most cases with a focus outside the thorax there was no lung lesion. If the lung infection was secondary to some other infection—as, for example, in the abdomen—the type of tubercle bacilli would be bovine, tuberculous foci in the lung yielded the human type of bacillus. The human bacillus had no predilection for lung tissue, feeding experiments had shown that the lesions produced by human and

bovine bacilli were the same, the greatest concentration of infection being abdominal. This point had an interesting confirmation in the work of Scott in Hong Kong. In conclusion Dr Cant showed, for Dr Hadfield of Bristol, five museum specimens from five consecutive cases of children dying of tuberculosis in which Dr Hadfield had been able to demonstrate the primary lung focus.

Dr P. T. ARMAND-DEILLE (Paris) said that, contrary to general opinion tuberculosis in children was found in the varied adult types. Most valuable information was to be obtained from comparing lung shadows and autopsy findings. He described his technique for the study of lungs post mortem in their proper relative positions and showed how it was possible thus to find every important lesion and compare it with x-ray shadows. Investigation on the lines might reveal one of two conditions—tuberculosis apparently limited to the tracheo-bronchial glands, or associated with different forms of lung tuberculosis. In nearly every case careful examination indicated the primary lung lesions. These might be (1) diffuse miliary tuberculosis in its various forms, (2) localized lesions, usually broncho-pneumonic lobar infiltrations, (3) unilateral lesions of a whole lung and (4) bilateral terminal lesions. His experience had convinced him that normal lungs showed x-ray hilum shadows which bore no relation to enlarged bronchial glands. Even when the glands became enormous caseous tumours their shadows might be lost in the larger shadow of the cardio-vascular apparatus. Post-mortem findings were gradually aiding in the interpretation of lung shadows from a prognostic point of view, it was possible to correlate progressive modification in the character of shadows with analogous anatomical evolution. Tuberculous bronchial gland tumours frequently occurred in the middle of the mediastinum where their shadows could but rarely be observed because they were usually masked by the cardio-vascular apparatus. So-called 'petitular shadows' were not produced by the glands. The primary focus was seldom detectable in the x-ray picture as it was often localized at the opposite pulmonary base behind the shadow of the heart, liver, stomach, or spleen. In lung lesions a study of well taken plates might reveal miliary tuberculosis before the characteristic signs and symptoms had appeared. It was difficult from x-rays alone to arrive at the accurate diagnosis of the type of pathological lesion present. A series of x-ray photographs during treatment showed progressively disappearing shadows while tubercle bacilli were still found in the sputum. Dr Armand-Deille illustrated his remarks with many beautiful slides of sections and comparative x-ray plates.

#### VOMITING AFTER OPERATIONS ON THE STOMACH

BY

A RENDLE SHORT M.D. B.S. FRCS,

SURGEON TO THE BRISTOL ROYAL INFIRMARY

VOMITING coming on within a day or two of an operation on the stomach whether a gastro-jejunotomy, partial resection or other surgical procedure is not uncommon and may be serious or even fatal. In some cases it is merely due to the anaesthetic or to blood in the stomach. In that event it is likely soon to cease. Repeated vomiting that persists for days and puts the patient in danger, may be due to one of the following causes:

1. **Vicious Circle**—Years ago this was frequent and often fatal nowadays in good hands it is seldom seen. It is due of course to a bad lie or the efferent loop or jejunum the afferent loop may have been too long or the efferent loop may fall away from the opening in the stomach so sharply that the duodenal contents re-enter the stomach and cannot find a way out. The vomit is copious and contains abundant bile. Prevention as such is only necessary to use a short afferent loop or jejunum in the operation of gastro-jejunotomy and to insert a suture, after completing the anastomosis to anchor the efferent loop to the transverse mesocolon in such or two to the

right of the hole in the mesocolon, and this complication will not be seen.

**2 Infection of the Suture Line**—Several French surgeons maintain that vomiting beginning a couple of days after the operation may be due to infection of the peritoneum around the suture line. It is quite possible that this may be true, but I have no recollection of seeing it.

**3 Adhesion of the Suture Line**—I am persuaded that the commonest cause of persistent and sometimes dangerous vomiting after gastric operations is a sticking together of the anterior and posterior suture lines in the mucosa. Of course, a careless surgeon may actually sew them together, but my rate is a point or two, but apart from this gross technical error it is possible for the cut edges to adhere. If this occurs there is no copious and persistent vomiting, which differs from that of vicious circle in that no bile is brought up. The chyme cannot enter the stomach, and the gastric contents cannot leave it. I first learnt of this danger after performing gastro-jejunostomy for pyloric ulcer.

The patient a woman, vomited about twice a day for three days, bringing up all she took and much gastric juice besides, but no bile. I reopened the abdomen, and found the stomach very large and tense but the jejunum empty. On opening the jejunum and inserting a finger it was perfectly plain that the anterior and posterior edges of the anastomosis had stuck together. It required some little force to separate them, but they were not bridged by a stitch. After various other complications she recovered.

A few weeks later a patient with cancer, on whom I had performed a partial resection by the Polya technique, began to vomit the day after operation, and brought up all she was given and much gastric juice besides, for three days. I reopened, and found a huge tumor in the distended stomach and an empty jejunum. Here also exploration with a finger inside showed that the suture line had adhered badly, but there was no stitch bridging it. She died.

These two cases brought to my mind other patients at an earlier date, who gave me great anxiety for a few days by persistent vomiting, which then stopped. It is quite likely, of course, that sufficient pressure might be developed in the stomach to force the passage, in fact, in both my cases the stomach was extraordinarily tense. If that happened the condition would be relieved.

In my opinion, then, adherence of the suture line is a not uncommon, and potentially very serious, complication of gastric surgery. Fortunately it is easily prevented. Ever since the experience related above I have inserted a piece of corrugated rubber dam, a little larger than a postage stamp, within the lumen of the anastomosis, fixing it by a fine catgut stitch to the mucosa of the stomach so as to overlap the suture line and point the way to the efficient loop of jejunum. I have had no trouble with vomiting after stomach operations since adopting this device. If it be objected that one has to take the clamps off before completing the interior suture line, in order to insert the piece of dam, the reply is that that ought to be done in any case to make certain that there is no bleeding. Intestinal anastomoses can be made safe and pervious by the same device.

## THE ETIOLOGY AND TREATMENT OF PSORIASIS

BY  
J. H. HEANEY, M.D.

The baffling nature of the cause of psoriasis is illustrated by the fact that one dermatologist has even called in the aid of embryology to show in analogy with the scales of lizards. He suggests that psoriasis is a "hark back" defence against cold, since it occurs almost invariably on the elbows and knees, which are the most thinly protected.

The most obvious proposition is that psoriasis is a parasitic disease, but there is no cultural or microscopic confirmation of this. The circumstantial evidence consists in (1) well authenticated cases of direct infection, (2) the marginal method of extension, (3) an observed connexion with osteoarthritis, (4) the fact that psoriasis resembles rheumatism in seasonal incidence and tendency to remission, and (5) the curative action of parasitocidal medicaments.

There can be no doubt that poison attacks the skin by way of the blood stream, just as it appears certain that

seborrhoea, in the beginning at least, is a more or less widely spread local infection connected with the bottle bacillus, and later associated with certain cocci. Confirmation of this is afforded by the sudden outbursts of activity in old-standing cases, by the symmetrical distribution of the lesions in acute cases, and by acute forms accompanied by asthma and headache, the last named suggesting sensitization. The evidence adduced in favour of other causes is so unconvincing that it might almost be cited in favour of the parasitic theory.

It has been suggested that psoriasis is a stage of seborrhoeic dermatitis, and the case of a patient, now aged 50, who has been under observation for some years will illustrate what is meant. The disease began as a profuse dandruff in early youth, later greasy scaly patches appeared, and still later dry patches on the scalp, followed by dry "spots" here and there on the body. Dry patches subsequently developed on the elbows and lumbar region, and still later extensive dry scaly patches on both shins. This, with two acute attacks of "spots" on the face and hands, extended over the age period 14 to 50. There is now baldness of the seborrhoeic character and very little dandruff, a psoriatic patch on the lumbar region, some involvement over the elbows and shins, and a few patches more truly seborrhoeic in type here and there on the body.

Beginning on the head and extending downwards, this is a classical case of seborrhoea, but if the history and the uppermost lesions are ignored there remains a typical psoriasis of the back, elbows, and shins, extending upwards or not at all. Some say that the two diseases may coexist. At first sight the view that psoriasis is a stage of seborrhoea appears temptingly obvious. What more likely than that a seborrhoeic dermatitis is the forerunner of psoriasis, sometimes in the same subject, as possibly in the case described, or that a seborrhoeic ancestor may have descendants with bald heads and a typical psoriasis beginning below? It is not disputed that a tendency to baldness is hereditary, and it is generally conceded that there is a predisposing disposition to psoriasis.

If it be taken for granted, then, that one of the factors in seborrhoea becomes "fixed" in the blood, and later may cause a psoriasis, which is it? The vegetable parasites to which the bottle bacillus belongs do not usually, if ever, set up blood sties, but the cocci do. Moreover, a vaccine of the bottle bacilli has no effect on psoriasis. On the other hand, chrysarobin has a special lethal effect on vegetable parasites and an almost specific action on psoriasis. Used locally in various strengths it is stimulant or irritant, it may stimulate growth of hair or cause a dermatitis. It has a special action on primitive vegetable organisms, and kills the spores of ringworm. Two local actions stand out therapeutically, the stimulant and the parasitocidal. Recently a patient with chronic psoriasis came under observation. The eruption was almost universal, and the irritation and fall of scales were such that it was feared chrysarobin might precipitate a pityriasis rubra. No treatment had any effect until chrysarobin was prescribed. It is difficult to think of a stimulant effect here. There remains the parasitocidal action and the further possible effect of absorption into the blood stream.

Whitla wrote forty years ago that chrysarobin ointment rubbed into one side of the body alone cured the lesions on the opposite side, such an event could only happen through the agency of the blood. How does chrysarobin act in the blood—directly, as silver does, or indirectly? If indirectly, it is possible that, since chrysarobin taken by the mouth induces a rise of temperature, it might give rise to a copula and complement of its own. The complement, not being specific, might unite with the copula of the disease—another instance of complement deviation—and in that way, or partly in that way, might effect a cure. This would presume a previous deficiency of complement in the blood. Apart from psoriasis, if it were found that chrysarobin was a ready and efficient means of producing complement, its use might become greatly extended.

On the other hand, chrysarobin may act directly on the "poison" both in the blood and in the skin lesions. It is found that the typically seborrhoeic lesions respond better to mercury and tar, but that the dry and more

chronic ones require chrysarobin. This would point to the presence of a particularly obstinate descending of the bottle bacillus in these lesions, and to the predominance of the bottle bacillus in it. And the special cocci in the more scabrous lesion. In conditions due to the bottle bacillus, such as dandruff nothing answers better than chrysarobin in weak strength, but where there is a combination of the bacilli and cocci as in the scaly, greasy form, chrysarobin shows only irritative properties and does harm, mercury and tar being much more efficient.

For use in the case described above a 0.2 per cent colloidal solution of chrysarobin was made by Messrs Crookes with a view to intravenous use, it is not stable in strong solutions at present. Quick progress in so chronic a case is not to be expected but the results are far better than any hitherto obtained. A daily dose of 30 drops in water one hour after dinner is being given by the month and the solution is well rubbed into the lesions night and morning with a pledget of cotton wool. The scales are not previously removed they seem to become partly absorbed where healing is occurring. This solution is the best I have yet tried for dandruff and seems to promise a permanent cure after short use. It does not discolour the hair, but rather gives it a gloss.

It might be concluded then on observed facts and the result of treatment—principally the differing actions of chrysarobin—that scabrous is the forerunner of psoriasis. Just as we find a gouty joint in the thin rhaemic descending of a ruddy and gouty ancestor so psoriasis may occur in the classically accepted form without concomitant sign of its scabrous ancestor. What has been said about treatment was in the first place intended to clarify the etiology but seems of some importance in itself. Thus the suggested intravenous injections in properly calculated doses might effect a permanent cure of even the most inveterate psoriasis.

It may be added that in the case of seborrhoea recorded acute gout developed at the age of 36, but the two diseases showed no other common factor except the general good health of the subject.

## DIRECT OBSERVATION OF THE CIRCULATION IN THE LIVING LIVER

BY

JAMES M. McQUEEN, M.B. CH.B. B.Sc.,

HALE-OWEN WORKS, LIVERPOOL

Using one quarter to half sized toads (pithed) I have been able by living a lobe of the liver on a sheet of glass on the microscope stage to observe the circulation of the blood in the liver sinusoids and branches of the hepatic vein under a low power. No coverglass is required and no solution of any sort is put in contact with the liver. The liver cells are clearly seen and the course of the blood flowing in the sinusoids (capillaries) can be accurately followed.

The liver circulation is now open to direct observation. Some years ago Leonard Hill greatly extended the microscopic study of the living tissue by his observation of the circulation in the glomerulus of the kidney and the principle guiding me was the belief that organs apparently too thick for direct observation under the microscope in the adult might not prove so if the observation was made at an earlier stage of growth.

I have noted several times that a pulse may be apparent in the liver sinusoids and in branches of the hepatic veins. It appears to be a pulse of arterial blood current due to the contraction of the auricle. It will be easily understood that the blood flows from the liver through auricle into ventricle during diastole of the auricle and ventricle and when the auricle contracts there is a retardation of the blood current in the liver sinusoids and hepatic veins.

Hence the description given by Sir James Mackenzie in his treatise on the heart is confirmed in great part. If the auricle is able to contract the pulsation in the liver sinusoids and hepatic veins is auricular in time—that is the a wave of the liver pulse is more or less synchronous with the a wave in the jugular pulse. If

the auricle fibrillates and no proper contraction occurs it acts as a passive receiving chamber, and the a wave of the ventricle becomes the retarding agent on the circulation in the liver sinusoids and hepatic veins. Or cause this retardation of blood current would be propagated to some extent to the portal vein and to the hepatic artery. Hence the pulse described in the portal vein must have, as one of its factors of origin, this retardation.

Mackenzie believed at one time that the auricle would have to be hypertrophied to produce an auricular form of liver pulse. He also believed an auricular form of liver pulse was a sign of tricuspid stenosis. Latterly he has stated in his treatise found cases of auricular liver pulse with no stenosis of the tricuspid valves. Drs. Turnbull and Weil described such a case.

It will be seen from the foregoing observations that an auricular form of pulse must exist in the liver because the pulse is created in great part simply by retardation and arrest of the blood flow out of the liver. On systole of the auricle the liver swells as the blood flow is arrested because blood is continuously coming to it by the hepatic artery and the portal vein. The demonstration of that pulse is a matter of technique. It would be easier to demonstrate with swelling of the liver sinusoids in cardiac disease and enlargement of the organ. It would not require any hypertrophy of the auricle or tricuspid stenosis to be present. The auricle not only distends the liver—it dams the outflow. Of course regurgitation or blood into the hepatic veins would add to some extent to the distension of the liver.

It is obvious that the shock of retardation of blood flow falls in great part on the liver cells. This shock is greatly increased when the auricle is practically non-contracting and the ventricle in its systole regurgitates blood through the auricle to the inferior vena cava. The blood pressure in the liver sinusoids must rise and pulsation with increased capillary pressure is always damaging to cell life. It is apparent in bedsores where the capillary pressure in the area of contact with the bed is raised by the compression of the venous outlets towards the valve or the pressure in the entering arteries. Increased pressure in the capillaries with pulsating shock is disintegrative of cell life.

In the cardiac liver Sims Woodhead notes (*Practical Pathology* p. 253)

that the central or hepatic vein is considerably dilated and the lobules are distinguished more readily than in the normal liver. The capillaries leading to the central opening are also dilated. The liver cells between the dilated capillaries are atrophied, etc. Later the liver cells may have disappeared from the immediate neighbourhood of the central vein.

It will be noted from this description that the pathology follows physiological findings. The pulse of retardation (auricular form normally present) when exaggerated falls first on the hepatic veins and the liver sinusoids that feed them. Similarly with the ventricular form or pulse of retardation.

But the liver pulse differs from any other form of pulse in that it has three components.

A The retardation of blood flow by the shutting off at the wave of the blood stream through contraction of the auricle.

B Where the auricle is passive as a shuttering agent the ventricular systole acts similarly. In both A and B some blood may be driven back into the hepatic veins but more in the case of B.

C While A or B in operation the liver swells through the entry of fresh blood by the portal vein and hepatic artery.

Consequently the fall in the liver pulse tracing is due to blood flowing unimpeded out of the liver.

This method of direct microscopical investigation of the liver will lead to further results. The pressure in the liver sinusoids will be measured and light thrown on the problem of the formation of liver lymph. The reactions of liver sinusoids (capillaries) to various stimuli etc. are now open to investigation. The question of nerve stimulation and its effects on the liver will no doubt be finally submitted to direct visual examination, and perhaps in the future micro-chemical reactions in the living animal may reveal something of the working of the liver.

I am indebted to the Medical Research Council for the loan of apparatus.

THE CLINICAL VALUE OF ANDREWES'S DIAZO  
TEST IN RENAL INEFFICIENCY.

BY

G. A. HARRISON,\* B.A., M.D. CANAD.,

AND

L. F. HEWITT,† Ph.D., B.Sc. LOND.

(From the Department of Chemical Pathology, St. Bartholomew's Hospital and College, and the Hale Clinical Laboratories, the London Hospital.)

In 1924 C. H. Andrewes<sup>1</sup> described an unexplained diazo colour reaction which he found only in uraemic serums. He was working on van den Bergh's test, and noted this peculiar colour reaction incidentally. His procedure was as follows:

To one volume of serum two volumes of alcohol were added. The mixture was centrifuged and the alcoholic supernatant layer removed. To four volumes of this alcoholic extract were added two volumes of alcohol and one volume of freshly prepared diazo reagent, as in van den Bergh's test. In a narrow tube the mixture slowly developed a brown buff colour. It was often necessary to let this mixture stand for twenty-four hours at room temperature to obtain full colour development. At the end of this time an addition of a slight excess of strong soda solution (10 to 40 per cent) produced a cherry red colour. This latter was the characteristic part of the test. The colour was fleeting. It lasted for a few seconds up to half an hour or so, depending on the concentration of the unknown substance responsible for the colour.

Andrewes obtained a positive reaction in eight cases of uraemia with blood ureas ranging from 220 to 650 mg. per 100 c.c.m. Five other cases of nephritis with blood ureas of 40 to 275 mg. gave negative reactions. Twenty-two other patients suffering from various diseases gave negative reactions. Normal serums were negative (Tables I and II). Andrewes made a number of experiments to try to discover the cause of his reaction. He excluded urea, uric acid, creatinine, and proteins. Normal urine, he stated, did not give the reaction. In only one out of three instances in which the cerebro-spinal fluid was examined was a positive reaction obtained, and in this there was slight contamination with blood. In three rabbits with blood ureas of 100 to 300 mg. per 100 c.c.m. the reaction was negative. Two of these had experimental nephritis.

L. F. Hewitt<sup>2</sup> confirmed Andrewes's work. He found the reaction limited to uraemia. He simplified the method as follows:

After adding the diazo reagent to the alcoholic extract of serum or plasma the mixture was boiled thoroughly for about half a minute. The maximum brown buff colour was thus obtained in a few seconds instead of twenty-four hours. The soda was added at once while the solution was still hot. The reaction has become very simple and a serviceable clinical test.

Hewitt's tentative suggestion, after performing a large number of chemical experiments to ascertain the cause of the reaction, was that a cyclic amine such as histamine or tyramine might be responsible. Contrary to Andrewes's experience, Hewitt found that alcoholic extracts of urines sometimes gave a reaction which appeared very similar to that in the blood. He noted negative reactions in two infants with uraemia and high blood ureas. In each of these cases there was hyperbilirubinaemia instead of the

H. C. Canda confirmed the value of Andrewes's reaction in patients with marked retention of waste products due to kidney damage. He found positive reactions before the blood creatinine reached 5 mg. per 100 c.c.m. One of his cases with an initial positive reaction recovered. He suggested that defective elimination was probably not the only factor responsible for the reaction. Becher<sup>3</sup> in Germany published a paper on the diazo reaction in alkaline solution shortly after Andrewes, but his technique was essentially different from that of Andrewes, and from our own work. We are satisfied that Becher's reaction could not have been given by the substance responsible for Andrewes's reaction.

Blotner and Fitz<sup>4</sup> in the United States of America obtained positive reactions in cases with much lower blood

ureas than has been experienced by other workers (Tables I and II). They made the following additional points:

(a) The reaction was of prognostic value in clinical work. A high blood urea was not so significant when accompanied by a negative, as when accompanied by a positive, reaction. The test was of value in differentiating renal coma from other types of coma.

(b) The reaction was positive in two nephrectomized rabbits one or two days after removal of the kidneys.

(c) A dog was nephrectomized, and when Andrewes's reaction was positive an extract of about 33 c.c.m. serum was made, partially purified, dissolved in physiological saline, and injected intravenously into a rabbit. The rabbit showed no toxic symptoms.

(d) The ascitic fluid of a human patient gave a positive reaction. The cerebro-spinal fluid did not.

The following tables summarize most of the findings of the above workers, and include our own subsequent work.

TABLE I—Andrewes's Reaction in Plasma or Serum

Author	Reaction Positive	Reaction Negative
Andrewes 1924	8 uraemics	5 nephritics 22 miscellaneous diseases 2 rabbits with nephritis Normal human serums
Hewitt 1925	12 uraemics	Many miscellaneous diseases in children 2 uraemic infants with hyperbilirubinaemia
Rabinowitch 1925	8 uraemics	Many miscellaneous diseases 4 cases of typhoid 12 cases of arterial sclerosis or nephritis
Blotner and Fitz 1927	35 cases with marked renal insufficiency 2 nephrectomized rabbits 1 nephrectomized dog	Several hundreds of cases with miscellaneous diseases 170 cardio-renal cases
Harrison	13 uraemics	17 kidneys diseases 25 miscellaneous diseases 4 normal
Hewitt	22 uraemics	18 kidney diseases Many miscellaneous diseases in adults
	Total 93 human cases	

We may conclude from Table I that in all probability the reaction is confined to uraemia, or at any rate to severe renal inefficiency. A negative reaction, however, does not absolutely exclude the diagnosis of uraemia.

TABLE II—Relation of Andrewes's Reaction to Urea Retention

Author	Positive Diazo			Negative Diazo		
	Cases	Blood Urea mg per 100 c.c.m.		Cases	Blood Urea mg per 100 c.c.m.	
		Max	Min		Max	Min
Andrewes, 1924	8	650	220	5 rabbits	275 100	40 100
Hewitt, 1925	12	692	240	—	—	—
Rabinowitch 1925	8	450	152	12	225	33
Blotner and Fitz 1927	7	107	60			
	8	171	103			
	10	223	172			
	7	321	224			
	4	536	322			
	36	536	60			
	2 rabbits	725	311			
Harrison	13	633	154	34	370	22
Hewitt	22	725	114	18	300	50

The results in Table II confirm Andrewes's conclusion that nitrogenous retention always accompanies retention of the substance responsible for his reaction, but that urea retention and his reaction do not run strictly in parallel. We have noted that the reaction is not confined to any one of the different clinical types of uraemia. In general the reaction becomes more marked as the uraemia becomes more severe clinically. The following findings in one case are given in illustration (Table III).

\* A report to the Medical Research Council.

† Working under the auspices of the Freedom Research Fund.

TABLE III

Date	Clinical Notes	Andrews Reaction	Effect of 100 c.c. of 10% NaCl
July 11 1925	La Colle	At a time	141
August 16th 1925	—	At a time	117
October 6th 1925	First convulsion on October 1st	At a time	1.3
December 1st 1925	Second convulsion on December 1st	At a time	212

TABLE IV — Findings in Cerebrospinal Fluid in Andrew's Case  
Perfection is 1.5 in 100 c.c.

Author	Andrews Reaction Positive No. of Cases	Andrews Reaction Negative No. of Cases
Andrews 1925	1	2
Harris 1925	0	1
Brown and Fitz 1927	0	1
Harris	0	2
Harris	0	3
In a case of F and Bloch and Fitz 1927	1	0

It appears probable that the substance responsible for Andrews' reaction does not pass into the cerebro-spinal fluid. It seems to have come into the cerebro-spinal fluid in the point has been tested. In this connection we would add that we have been unable to obtain a positive reaction with an alcoholic extract of the corpuscles separated from serum which give strongly positive Andrews' reactions. The substance responsible for the reaction therefore probably does not diffuse into the red corpuscles or only to a slight degree.

In a paper one of us (L. F. H.) published in 1925, it was noted that in two cases of uraemia in infants with megaloblastic reactions there was hyperbilirubinaemia in the blood. In the usual hypobilirubinaemia we have since counteracted a third case. The patient an adult with clinically uraemic and the blood urea was 320 mg. per 100 c.c. of blood. There was in addition severe jaundice with marked hyperbilirubinaemia and bile in the urine. Andrews' reaction was however negative. We thought at first that there might be some connexion between the hyperbilirubinaemia and the negative Andrews' reactions but subsequently four cases have been encountered in which hyperbilirubinaemia was associated with positive reactions.

In conclusion Andrews' reaction is so little known that a brief outline or the simplified method may be of value.

**Simplified Method**

Reagent (identical with those used in van den Bergh's test)

**Solution A**  
Sulphanilic acid  
Concentrated hydrochloric acid  
Diluted with water

**Solution B**  
Sodium nitrate  
Diluted with water

The diazo reagent is prepared by mixing 25 c.c. of solution A with 0.75 c.c. of solution B. The mixture may be kept for at least 24 hours at room temperature without loss of sensitivity. So far as Andrews' reaction is concerned although of course the test. The mixture often turns highly yellow after keeping for a day or two but this does not matter in van den Bergh's test. Serum or oxalated plasma is obtained from the patient in the usual way. Post mortem blood from a case of uraemia in which the reaction though our impression is that the reaction obtained after death does not give so strong a reaction as the serum obtained from the same patient shortly before death. So per cent. are added. The precipitated proteins are separated by centrifuging or filtering. (A lightly improved extraction may be obtained by heating the mixture of serum and alcohol to the boiling point.) To four volumes of the filtrate one volume of the diazo reagent is added. The mixture is boiled thoroughly for half to one minute and a solution of 10 per cent. soda is added drop by drop shaking after each addition. The soda may be added immediately after the boiling.

The colour change on making alkaline with soda is the essential part of the reaction. The test should be called positive only when a definite pink or cherry red colour is seen. This pink colour is fleeting. It may last for a few seconds only and the mixture thus therefore be observed carefully whilst adding the soda. In a few very severe cases of macraemia the pink colour may persist for longer periods even up to half an hour. The test in its present form is only qualitative. We have found that the volumes recommended may be judged sufficiently well by eye without exactly measuring the sensitivity of the reaction.

On boiling the mixture or protein-free filtrate and diazo reagent a yellow brown colour always results in positive cases but a similar colour may also be obtained in negative cases. We have found that substances other than that it is possible for Andrews' reaction may give a yellow brown colour at this stage (in acid solution) but that these other substances do not yield a red colour on alkalinization.

One of us (G. A. H.) has established a clue as to the nature of the substance responsible for Andrews' reaction but the work is not so advanced as to allow of a definite statement here. It may be mentioned however that the substance is certainly present in normal urine.

**Summary**

- 1 A positive Andrews' diazo test is only found in uraemia or severe renal insufficiency. A negative reaction, however, does not exclude uraemia.
- 2 The unknown substance responsible for the reaction does not appear to pass into the cerebro-spinal fluid and is either absent from or present only in minute quantities in the red blood corpuscles. The blood of uraemics obtained post mortem often gives the reaction.
- 3 Nitrogenous retention always accompanies retention of the substance responsible for the reaction but uraemia, retention and Andrews' test do not run strictly in parallel.
- 4 An outline of the simplified method is given. It is claimed that the reaction has become a simple clinical test.

Andrews C. H. 1925, 1926, 1927, 1928, 1929, 1930, 1931, 1932, 1933, 1934, 1935, 1936, 1937, 1938, 1939, 1940, 1941, 1942, 1943, 1944, 1945, 1946, 1947, 1948, 1949, 1950, 1951, 1952, 1953, 1954, 1955, 1956, 1957, 3146, 3147, 3148, 3149, 3150, 3151, 3152, 3153, 3154, 3155, 3156, 3157, 3158, 3159, 3160, 3161, 3162, 3163, 3164, 3165, 3166, 3167, 3168, 3169, 3170, 3171, 3172, 3173, 3174, 3175, 3176, 3177, 3178, 3179, 3180, 3181, 3182, 3183, 3184, 3185, 3186, 3187, 3188, 3189, 3190, 3191, 3192, 3193, 3194, 3195, 3196, 3197, 3198, 3199, 3200, 3201, 3202, 3203, 3204, 3205, 3206, 3207, 3208, 3209, 3210, 3211, 3212, 3213, 3214, 3215, 3216, 3217, 3218, 3219, 3220, 3221, 3222, 3223, 3224, 3225, 3226, 3227, 3228, 3229, 3230, 3231, 3232, 3233, 3234, 3235, 3236, 3237, 3238, 3239, 3240, 3241, 3242, 3243, 3244, 3245, 3246, 3247, 3248, 3249, 3250, 3251, 3252, 3253, 3254, 3255, 3256, 3257, 3258, 3259, 3260, 3261, 3262, 3263, 3264, 3265, 3266, 3267, 3268, 3269, 3270, 3271, 3272, 3273, 3274, 3275, 3276, 3277, 3278, 3279, 3280, 3281, 3282, 3283, 3284, 3285, 3286, 3287, 3288, 3289, 3290, 3291, 3292, 3293, 3294, 3295, 3296, 3297, 3298, 3299, 3300, 3301, 3302, 3303, 3304, 3305, 3306, 3307, 3308, 3309, 3310, 3311, 3312, 3313, 3314, 3315, 3316, 3317, 3318, 3319, 3320, 3321, 3322, 3323, 3324, 3325, 3326, 3327, 3328, 3329, 3330, 3331, 3332, 3333, 3334, 3335, 3336, 3337, 3338, 3339, 3340, 3341, 3342, 3343, 3344, 3345, 3346, 3347, 3348, 3349, 3350, 3351, 3352, 3353, 3354, 3355, 3356, 3357, 3358, 3359, 3360, 3361, 3362, 3363, 3364, 3365, 3366, 3367, 3368, 3369, 3370, 3371, 3372, 3373, 3374, 3375, 3376, 3377, 3378, 3379, 3380, 3381, 3382, 3383, 3384, 3385, 3386, 3387, 3388, 3389, 3390, 3391, 3392, 3393, 3394, 3395, 3396, 3397, 3398, 3399, 3400, 3401, 3402, 3403, 3404, 3405, 3406, 3407, 3408, 3409, 3410, 3411, 3412, 3413, 3414, 3415, 3416, 3417, 3418, 3419, 3420, 3421, 3422, 3423, 3424, 3425, 3426, 3427, 3428, 3429, 3430, 3431, 3432, 3433, 3434, 3435, 3436, 3437, 3438, 3439, 3440, 3441, 3442, 3443, 3444, 3445, 3446, 3447, 3448, 3449, 3450, 3451, 3452, 3453, 3454, 3455, 3456, 3457, 3458, 3459, 3460, 3461, 3462, 3463, 3464, 3465, 3466, 3467, 3468, 3469, 3470, 3471, 3472, 3473, 3474, 3475, 3476, 3477, 3478, 3479, 3480, 3481, 3482, 3483, 3484, 3485, 3486, 3487, 3488, 3489, 3490, 3491, 3492, 3493, 3494, 3495, 3496, 3497, 3498, 3499, 3500, 3501, 3502, 3503, 3504, 3505, 3506, 3507, 3508, 3509, 3510, 3511, 3512, 3513, 3514, 3515, 3516, 3517, 3518, 3519, 3520, 3521, 3522, 3523, 3524, 3525, 3526, 3527, 3528, 3529, 3530, 3531, 3532, 3533, 3534, 3535, 3536, 3537, 3538, 3539, 3540, 3541, 3542, 3543, 3544, 3545, 3546, 3547, 3548, 3549, 3550, 3551, 3552, 3553, 3554, 3555, 3556, 3557, 3558, 3559, 3560, 3561, 3562, 3563, 3564, 3565, 3566, 3567, 3568, 3569, 3570, 3571, 3572, 3573, 3574, 3575, 3576, 3577, 3578, 3579, 3580, 3581, 3582, 3583, 3584, 3585, 3586, 3587, 3588, 3589, 3590, 3591, 3592, 3593, 3594, 3595, 3596, 3597, 3598, 3599, 3600, 3601, 3602, 3603, 3604, 3605, 3606, 3607, 3608, 3609, 3610, 3611, 3612, 3613, 3614, 3615, 3616, 3617, 3618, 3619, 3620, 3621, 3622, 3623, 3624, 3625, 3626, 3627, 3628, 3629, 3630, 3

to light and accommodation. The condition of the lower extremities was similar to that already described, but very much improved.

On the twenty-third day the patient complained of pain on respiration. Nothing abnormal was found in the chest. There was a visible swelling of the abdomen and flank which gave the physical signs of fluid, as it extended from the umbilicus deep into the loin its colonic nature was dissimulated and only became evident after a copious motion. Acetone was still present in the urine in spite of large quantities of barley sugar and glucose lemonade.

The patient's subsequent progress was uneventful, and she was discharged ten days later somewhat emaciated, but able to walk. The systolic blood pressure was 105 mm. Hg. The knees and legs were still tender on the thirty-fifth day, and she had, according to the parents, attacks of drowsiness accompanied by flushing and puffiness of the face lasting about ten minutes.

The sister, M., has had no ill effects at all. Her hair had been clipped rather too short before we saw her, and to assist depilation we adopted the following plan. On the eighth day the scalp was treated with Unni's zinc gelatin and covered with a ceresine bandage. This was peeled off on the twenty-first day with very little discomfort, yielding a perfect "billiard ball." The hair in both cases has begun to grow.

Most of the symptoms described are explicable as the action of a poison on the nervous system, but the arthritis and periarthritis of the knee-joints, with which we are familiar as occurring nearly invariably to a lesser degree, seem to demand a different explanation. The constant presence of the condition seems to argue against the theory that thallium has a biotrophic influence towards some micro-organism capable of producing an arthritis.

### FOREIGN BODY IN THE BLADDER

I was recently called to a patient, aged 29, two months pregnant who had symptoms of cystitis and pelvic inflammation which had been going on many months. On passing a metal catheter I felt a hard foreign body in the bladder, and on questioning the patient she said she could not remember ever having inserted anything, so I concluded it was a case of calculus, especially as it had a distinctly stony feel. Mr. Frank Belben operated a week later and removed a piece of wood three and a half inches long by one inch wide, partly covered with calcareous deposit, evidently a peg-label for garden plants.

About a month later, when the patient had quite recovered, I inquired when she had put the wood there, and she said she had used it to insert some pledges of lint soaked in iodine lotion which I had ordered two days before the operation on account of the inflamed state of the vagina, and did not know the wood had remained inside. The calcareous deposit, of course, proved it to have been there much longer. The urethra appeared to be quite normal in size, but she assumed me that the insertion caused no pain or difficulty. If I had not been called in till the time of confinement the case might have ended as one of purpural septicaemia of unknown origin, as I should not have suspected the presence of the foreign body then.

### CONGENITAL UNUNITED FRACTURE WITH FALSE JOINT

The rarity of congenital ununited fracture gives the following case some interest.

A child, aged 3 years, was seen by me at a welfare clinic. The history was that the child was apparently normal when born, but a day or two after birth it was noticed that the right leg was deformed. On examination at the clinic both bones of the right lower leg were found ununited, a false joint was present at the junction of the lower and middle thirds of the leg. On the anterior aspect of the joint was a bursa, and the whole appearance resembled nothing so much as a second knee. A fair amount of movement was present, and the child could get about fairly well, using the normal or abnormal "knee" at will.

It is curious to note that the child had seen but two doctors, one shortly after birth, and myself almost three years later.

Assistant M.O.H., Sunderland

### TREATMENT OF SPIRILLUM FEVER WITH STOVARSOL\*

The wide prevalence in Africa of "spirillum" or "typhoid" fever indicates the need of obtaining some simple and safe treatment which could be entrusted to the ordinary intelligent native, when he is at a distance from skilled medical help. The stovarsol series provides a more or less certain cure, but these drugs cannot be put into the hands of an untrained native. Their use is not without danger, and the necessary outfit and technique prohibit their employment outside regular medical establishments. It occurred to me that stovarsol, successful and safe in its treatment of other spirochaetal diseases, would be worthy of trial as an alternative to the arsenobenzols, accordingly a test was undertaken in the Church Missionary Society's hospital at Toro, in Uganda. The success met with so impressed me that I feel justified in publishing the result.

When first using stovarsol I continued its administration longer than was necessary, I have now decreased the length of the courses of treatment without any failure of result. The clinical details were as follows.

Seven patients were treated with stovarsol, five being Europeans and two natives. One of the Europeans had previously had intravenous injections of novarsenobillon, but the others had had no treatment. In each case the spirochaetes of spirillum fever were found in the blood. The first two patients—one a European—were given the 4 gram tablets in water, in the early morning, four tablets being administered on the first day, five on the second day, six on the third and fourth days, five on the fifth day, and six on the tenth day, no relapse followed. The next two patients were given a four-day course, the first dose being administered immediately on the first signs of fever, and not, therefore, necessarily on an empty stomach. The first dose was four tablets followed on the next day by five tablets, and on each of the two successive days by six tablets in water, no relapse followed. The other three patients received only two days' treatment, six tablets being given each day, swallowed whole, followed by water. No toxic symptoms were seen and no relapse occurred.

Though this is too small a series for a dogmatic statement to be made I have no hesitation in advising others to test this drug. In treating patients with jaundice and syphilis I have used as large a dose as nine tablets in one day without ill effects. I consider, therefore, the administration to adults of six tablets, each of 4 grams, to be perfectly safe. I gave three supplies of stovarsol to an intelligent native pastor, who reported that three patients had been cured without relapse. I feel very hopeful that a real solution has been found of the difficulty of dealing with spirillum fever in districts far from medical help. Its diagnosis by the layman will depend on the characteristic tick fever headache, compared with which the headache of concussion has been described as trivial. The pains in the long bones are also marked, but the terrible intensity of the headache, which has led to suicide in some cases, should be the symptom upon which the layman is advised to act. The medical practitioner will be able to examine blood films for spirochaetes.

Toro, Uganda

### Reports of Societies.

#### INSOMNIA

At the meeting of the Medical Society of London on December 12th, with Mr. H. W. CROSON in the chair, Dr. E. M. CALLENDER opened a discussion on insomnia.

Dr. Callender said that the most striking fact in normal sleep was the partial or complete loss of consciousness due to lessened activity of the brain tissue, and particularly of the cortex cerebri. The first of the special senses to go was vision, the last was hearing, and during sleep the auditory sense was the most easily excited. Respiration became deeper and slower, the blood pressure fell, the pulse frequency was lessened, and knee-jerks were lost. Normal sleep varied in intensity during the night. For the first two hours there was a rapid increase in intensity, from the third hour onwards the depth of sleep became gradually less, but there had been observed to be a second period of intensity about the sixth hour. The periodical

\*Owing to limitation of space it has been necessary to abridge Dr. Schofield's original paper.

recurrence of sleep appeared to be due to fitful nature of the vasomotor centre in the medulla brought about by its continuous activity during waking hours. Insomnia might arise from any cause which disturbed this equilibrium, it made its appearance in states of excitement, worry, emotion of any kind, pain, fever, cardiac or respiratory disease, and extremes of arterial pressure. Sometimes it arose from external causes such as the noise of traffic or the unaccustomed tactile sensations produced by lying in a strange bed. The treatment of insomnia was the remedying of the underlying cause of ill health. When there was insomnia without illness the sometimes advised patients to try going to bed an hour or two later or to alter the hour at which the last meal was taken. In the case of aged and debilitated patients the administration of hot milk or some patent food in the middle of the night might cause a resumption of sleep. It was important to attend to the type of bed and bedding, the weight of the clothes and the temperature of the room. Many kinds of pain causing insomnia were relieved by a dose or two of aspirin. The misery of dental abscess might be relieved by the application to the face of a pepper plaster—flannel soaked in brandy peppered freely on one side and tied to the face with the pepper next the skin. Insomnia in patients with hyperpnea might be relieved by a good dose of calomel which acted as a hypnotic long before it acted as an aperient. Hypnotics should be avoided if possible but sleeplessness might cause such havoc that they must be given. It was a good principle never to use them until satisfied that it was really necessary to do so.

Dr COOPER HOLMES speaking from the neurological standpoint said that although insomnia was found in many forms of organic nervous disease it was usually due to the attendant pain or discomfort. It occurred as a primary symptom however in some conditions, of which encephalitis lethargica was an example. It was in psychogenic nervous disorders that the neurologist most frequently met with insomnia. Lack of sleep was one of the most common symptoms of neurasthenia of any origin. Occasionally insomnia was met with where no organic or psychogenic factor could be found. In some of these cases inability to sleep appeared to be constitutional or hereditary. In others insomnia had become a habit the patient repining to bed convinced that he could not sleep and therefore in no proper frame of mind to ensure slumber. In neurasthenia a change of environment was often required. Most normal people slept more soundly after exercise if not too fatiguing and this held also for some of the neuroses. Of physical treatments massage was the most important. He usually ordered general massage in the late evening, at least 90 minutes after the last meal. Hot baths of en provoked sleep but occasionally made patients more restless and wakeful. Drugs should not be employed if it was possible to do without them. The danger of hypnotics if these were prescribed with reasonable care and supervision had been exaggerated though the risk of abuse in dosage and prolonged administration was probably greater in the case of neurasthenic patients. Alcohol was perhaps safer than and as effective as any of the hypnotics. A glass of beer before retiring often secured a good night's sleep but it acted only with those not accustomed to alcohol the stronger spirits should be avoided. He thought that mednal was one of the safest and most efficacious of hypnotics.

Sir MATTHEW CRAIG said that in his earlier years he thought drugs a pernicious method of treatment for sleeplessness only to be resorted to in dire necessity but he had come to revise that opinion. Sleeplessness in the young was probably more damaging than in those of later age. The general practitioner often did wrong in allowing children to go with very little sleep with the result that they had digestive and other difficulties whereas a small dose of bromide would correct these. He thought it was a mistake to use the term 'sleeping draught'. Most of the sedatives were not sleeping draughts in the true sense of the word they would not produce sleep if given by day. These preparations acted only as a sedative to the nervous system, and the sleep that followed them was natural sleep. If mednal were given only by day the

patient would probably have a quiet day and sleep at night. Bromides were very valuable in small doses, but large doses were dangerous. They furred the tongue, upset the digestion, were toxic to the skin and confused the mind. Another drug which was regarded as safe was paraldehyde but it had great disadvantages. If a patient had been without sleep and was just becoming confused it was a most valuable drug for ensuring slumber but the danger was that it was excreted through the respiratory tracts and in some persons it caused the air tubes to be filled with mucus. He had used the barbituric acid group freely for many years and had never seen any bad effects other than minor difficulties such as rashes, which might arise from personal idiosyncrasy. Sulphonal was valuable with old persons. It was perhaps one of the best, but was toxic in its effects. When a sedative had been obtained which suited the person it should not be changed just because the person was beginning to sleep. The few persons who became addicts were of the type who would respond thus to any drug but he had seen very few cases of addiction, even including the following treatment with preparations of opium.

Sir WILLIAM WILLCOX thought that treatment of insomnia should not begin by resort to drugs but that general measures should be tried. In insomnia associated with delirium better results followed the application of a hot pack than a resort to drug. With neurasthenic patients it was necessary to give hypnotic drugs in some cases but caution should be employed. He believed that he had seen more cases of unfortunate results following the use of hypnotic drugs than most medical practitioners and had concluded that it was not only the unstable who became addicts. He thought that if the members of a first-class football team were given a dose of heroin every night for a month half of them would become addicts. A drug which was much less toxic than others was adalin bromural also was helpful.

Dr F M R WALSHES urged the need of a new orientation with regard to insomnia. He asked if insomnia was anything more than the absence of sleep or if there was more than one kind of insomnia and if the insomnias of an exciting neurosis or a nocturnal delirium and of high blood pressure were identical. Dr H A ELLIS reported observations of the specific gravity of the urine early in the morning and said that it was evident that in neurasthenia some faulty elimination during sleep accounted for subsequent wakefulness, one cause of which was the inability of the stomach to empty itself anything which would release the tightness of the sphincter or the stomach would do away with the common wakefulness in the middle of the night. Dr C P SIMONDS shared Dr Walshes's belief that the whole problem of sleep should be approached from a new physiological point of view in the light of the work of Pavlov. In many persons with the major complaints of insomnia and depression the latter was considered to be the result of the insomnia whereas they were really cases of mild depressive psychosis in which the insomnia and the depression were both symptoms of the same underlying condition. Dr COOPER LANE thought that absolute sleep was much less often attained than was supposed. It indeed was never attained at all. It seemed to him that in any condition in which the insomnia was the result of toxicemia from the accumulation of waste products little good was likely to be done by sedatives.

### THE ACTION OF SYNTHALIN

At the meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on December 13th with Professor J A GRAY, President in the chair a discussion took place on the action of synthalin, a synthetic preparation recommended for the treatment of diabetes to be given by the mouth.

#### Physiological Experiment

Dr H H DIX in opening the discussion commended himself to a consideration of the action of synthalin as appreciated by laboratory experiments. Others who followed

in the discussion would be able, as he was not, to deal with the question of its action on the diabetic patient. Synthalin was a guanidine compound, the discovery of which started from the observation that poisoning by guanidine itself was accompanied by a hypoglycemia. This fact suggested to Frank of Breslau that it might be worth while to search among guanidine derivatives for a substitute for insulin. The relation became more favourable as the carbon chain was lengthened by building up synthetic compounds, and ultimately, with ten carbon atoms, a compound was found to be sufficiently promising to warrant an extended clinical trial. The name of the compound was decamethylenediguandine, the formula of which Dr Dale displayed on the blackboard. According to Frank, synthalin lowered the blood sugar of a dog which had been made diabetic by removal of the pancreas, reducing it to or below normal level. It was also stated that in a diabetic dog the abnormal relation between the arterial blood sugar and the venous blood sugar in a limb was changed to the normal by injecting a large dose of synthalin—that is to say, the normal slight excess of glucose in the arterial over the venous blood was restored if a large dose of synthalin was given to the diabetic animal. In these cardinal features, therefore, the action of synthalin, at least superficially, seemed to resemble that of insulin, but it differed in certain important respects. The action of insulin, when given intravenously, began almost immediately, whereas the action of synthalin usually began to be manifest only after a delay of some hours. On the other hand, synthalin had the practical advantage that its action could be produced on oral administration, and so far as the speaker was aware this was the only method of the kind tried to any extent in practical medicine. A substance promising such convenience in administration as compared with the tiresome injections of insulin administration was certain to be given a ready trial.

It might be taken as a general rule, continued Dr Dale, that a new remedy which was going to establish itself as a permanent addition to therapeutic methods would find a substantial unanimity of approval quite early in its career. Its advantages early became so obvious that the ingenuity of many workers was attracted to the elimination of the drawbacks, whatever those might be. In recent medical history salvarsan and insulin might be taken as examples. There was another class of newly introduced remedies with regard to which a different course was taken. Here the enthusiasm engendered by a number of early optimistic reports soon showed a tendency to diminish as the opportunity of trial spread to a wider constituency. Experience served to discover new limitations and drawbacks, and in course of time remedies of this kind were apt to be superseded and to retain only an historical interest as stages on the way to something better, or, if they did find a more permanent use, it was a use in a much more restricted field than that which the first descriptions had appeared to open up. He was inclined to think—though he might not be interpreting the signs correctly—that synthalin would be found to belong to this second class. From his own point of view as an experimental physiologist the real interest of synthalin had been in a different direction. A substance having an action so similar to that of insulin in some features could not fail to have an interest as possibly giving a clue to some part of the quite unknown structure of insulin itself. From this point of view the matter of chief importance was to discover whether the hypoglycemia which synthalin could produce was the result of an action fundamentally similar to that of insulin, or whether the resemblance was merely superficial, and the hypoglycemia produced by its action of a different kind. Accordingly workers in his laboratory had carried out a number of experiments on the details of the action of synthalin in comparison with that of insulin. They repeated, in the first instance, the observations on its effect when administered to normal rabbits. For this purpose very large doses in comparison with those used in therapeutics had to be given in order to produce any definite effect at all, and even then the result was somewhat uncertain. The usual effect, during the first hour

or two, was a rise of the blood sugar percentage above the normal. That did not always happen, sometimes there was practically no effect on the blood sugar for an hour or so, and in an occasional rabbit the fall might begin quite early without any preliminary rise, and even without much latent period. But the usual course was a preliminary period in which the blood sugar rose to a varying degree above the normal, followed by a fairly rapid fall at the end of from four to six hours. If the animal was killed when hypoglycemia had once definitely appeared, the liver on analysis would be found to have lost practically all its glycogen. A second point was that when this hypoglycemia had been produced no measures to relieve it—not even the production of a lasting restoration of the blood sugar to normal—would save the animal's life. The dose necessary to produce hypoglycemia in the rabbit, therefore, was a generally toxic dose. A third point to be noted was that, even before a definite hypoglycemia had set in, adrenalin in doses which would normally produce a large rise in blood sugar failed to have any such effect.

The impression produced on his mind by these observations was that, while synthalin in sufficiently high doses would produce a great though delayed fall of blood sugar, these doses had to be large enough to produce a serious impairment of function of the liver. The one feature which could be regarded as having perhaps a fundamental resemblance to insulin—and not merely a superficial one—was the depression of new carbohydrate formation, which was suggested as one of the two main effects of insulin itself. But in insulin such an effect, if it was a true effect, was temporary and physiological, in synthalin there was so far no evidence that it was other than a permanent and toxic effect on the liver function. The fact was recorded clinically that synthalin might be unsuitable and even dangerous to patients whose livers were already unhealthy. Perhaps also the fact might be taken as pointing in the same direction that the means most widely advocated for counteracting the anorexia and nausea obtained with synthalin were the simultaneous administration of a bile acid, it was difficult to see why this bile salt should have a value in avoiding any anorexia and nausea produced by synthalin unless this was the result of a secondary action on the liver, and not a primary effect on the stomach itself. On a closer analysis, endeavouring to trace the glucose which disappeared with the administration of synthalin, the similarity between synthalin and insulin appeared no longer to hold. So far from the change in muscle-glycogen accounting for the glucose lost, it merely provided an additional loss, also needing explanation. Under no conditions had any change other than a loss been found in the muscle-glycogen as a result of synthalin. Although extra glucose was disappearing the muscles simultaneously lost—not gained—glycogen. It was quite clear that the glucose was not, in that form of experiment, disappearing in the same way as it did under the action of insulin. The next obvious possibility was that the glucose was being simply taken into lactic acid, that possibility was at the moment under experiment in his laboratory. He could only say, so far as information was available, that during that period of increased glucose disappearance, with diminished oxygen consumption, the fact that the respiratory quotient rose far above unity was certainly in favour of a change of glucose merely into lactic acid or kind, but further experiments were necessary.

his. If lactic acid were indeed the substance produced from the disappearing glucose it might in turn be built up into glycogen under the more favourable conditions of the intact living body, and when the dose of synthalin was not of such toxic dimensions as were found necessary in the laboratory in order to get the clear demonstration of this action.

In conclusion Dr Dale made a brief reference to another antidiabetic preparation called "glukhorment," which was put forward with the high authority of Professor von Noorden, Dr Dale, however, said that he had nothing to add to what he and Dr H. W. Dudley had written on this subject in the *BRITISH MEDICAL JOURNAL* (December 3rd, page 1027).

*Clinical Observations*

Dr G. GRAHAM said that reports of the clinical value of synthalin had varied greatly. The earlier workers in Germany had quite good results. In America Joslin had reported on a few cases and thought the substance worthy of further trial. From Montreal came similar reports. In this country Dr R. D. LAWRENCE had had disappointing results while the results obtained by Professor Melen and others had been rather more favorable. Dr Graham's own cases were twelve in number. These had been under the observation of his colleague Dr Linder and himself at St. Bartholomew's. He showed graphs relating to each patient. The first two cases in which synthalin was tried convinced him and his colleague that there was a definite action on the sugar in the blood and also in the urine though the normal blood sugar was not recovered. In the next four cases, as the result of experience, treatment was placed on a more scientific basis, but the attendant nausea and increase were found to be considerable. The toxic effects in many of the other cases were a very serious inconvenience. One child aged 6, was rendered very ill probably because too large a dose of synthalin was given. Of the 12 cases in 4 synthalin had very little effect indeed in the remaining 8 there was quite a definite result but in only 2 of these had synthalin treatment been continued, 4 had been given up on account of toxic symptoms, and 2 for other reasons. Synthalin undoubtedly had an action on the glycosuria but it worked very unsatisfactorily in this respect from insulin which practically always produced good results. It caused toxic effects, and there were no means of predicting which patient was going to suffer these and which was not. It was difficult to say whether synthalin had any place in the treatment of diabetes. For the patients who needed insulin and were willing to have it synthalin had no value at all at present in his opinion for those who were unwilling to have more than one dose of insulin and should have more doses synthalin might be of some help and for those who would do anything to avoid insulin although they needed it synthalin was worthy of trial. But the patient must be watched and the treatment stopped as soon as any untoward circumstance occurred.

Dr R. D. LAWRENCE said that his first experience of synthalin, from January to April of this year was discouraging. In two mild cases of diabetes synthalin had its usual effect in reducing glycosuria. He saw no effect on the ketosis in these cases and no increase in weight, strength or energy. In four severe or moderately severe cases he tried to substitute synthalin both entirely and partially, for the accustomed dose of insulin but he failed to produce any definite effect in sparing the amount of insulin. In one of them he thought he had spared 15 units of insulin, but when he stopped the synthalin again he found the case was adequately controlled by the same amount of insulin as was then being given and that apparently the patient had improved in her carbohydrate tolerance. The chief difference between his own series and that of Dr Graham was that many of Dr Graham's cases he thought, were on treatment for the first time (Dr GRAHAM About half of them). Cases which had not been previously treated either by diet or insulin for a long time were of very doubtful value from the experimental point of view. For the first two or three months—at any rate for the first month—one could always expect that the insulin at first required in large amounts might be considerably reduced afterwards. These cases of his own had been for a long period on a stable diet and had had very minor changes in their insulin. He had shown his results to Professor Frank when he was over in this country. Frank had no criticisms to offer as to the way in which he had used the synthalin, but said that he could not understand the results and that he had seen a considerable number of other cases in which it had been impossible to produce any effect with synthalin. He could only advise him to go on trying. Frank divulged the fact also that one could not go on with synthalin indefinitely and that even patients who tolerated it well for the first two or three weeks usually developed an intolerance after six, eight, or ten weeks when synthalin had to be stopped.

Of course, in such cases it was necessary then to readjust the diet or the insulin. The speaker therefore decided from his practical point of view that this drug which had to be interrupted and always to be under control was not of any great value in treatment. The next experience he had with synthalin was rather an unwitting one. Dr Dale had asked him to test the effect of "glukhormont" on diabetic patients, and he followed out two cases very carefully, changing them over to synthalin after they had been for a time on the other preparation. The results showed how similar—indeed, identical—were the effects with "glukhormont" and with synthalin, both in the reduction of glycosuria and in the production of the same toxic symptoms: anorexia and nausea, sometimes actual vomiting. One of these last two cases was the only one in which he had produced any satisfactory results with synthalin, here he got it to spare about 15 units of insulin a day. In his opinion synthalin possessed more disadvantages than advantages in the treatment of diabetes. The disadvantages were its frequently toxic action when given in efficacious doses (probably it was always at least mildly toxic), the uncertainty of its action, the fact that it could not spare much insulin in severe cases, and the fact that it could not be taken continuously, but must be intermittent, involving a readjustment of the diet and insulin. It was a brake upon metabolism, but (he thought) a toxic brake and there seemed to be no evidence that it built up the body or had the anabolic action which insulin possessed. In a word, he did not think that synthalin had brought anything of importance into the routine treatment of diabetes which still depended on diet and on insulin if necessary, and to introduce a doubtful factor could only complicate matters and do harm.

Dr P. J. CANNING said that he had done some experimental work, though not on the same scale as that carried out under Dr Dale. His results however had been very similar. In his experimental work the doses of synthalin given had corresponded as far as possible to the physiological or medicinal dose, and the huge doses of which Dr Dale had spoken were not employed. The main thing that came out from these experiments was that in most of the animals there was an effect on the blood sugar generally coming on about two hours after the animal had taken 2 mg. per kilo of body weight but the maximum effect of synthalin was not seen until after about twenty or twenty-two hours. In quite a number of rabbits the blood had been examined every hour for forty hours and the maximum effect was found to appear at the twentieth or twenty-second hour after the normal dose. The drop extended from about the second hour to about the twenty-second but the rise up to the thirtieth hour was much more rapid when as a rule the blood was back again at its fasting normal level. His clinical experience of synthalin was limited: the cases he happened to get hold of were perhaps not suitable. From the recorded cases it appeared that success was most pronounced in elderly patients and his experience was that the diabetes of the elderly patient—over 45 or 50—was really not the same thing as the diabetes of the younger and that was the reason probably why synthalin acted better with the former. It was likely that the diabetes of the elderly was essentially a liver condition and that synthalin had some slowing effect upon the metabolism there and so proved to be more beneficial than in the young patient who probably was essentially and primarily suffering from a pancreatic defect.

Dr DALL in reply, said that the plan he and his colleagues had adopted ordinarily indefensible had been to examine the effects of abnormal toxic doses or a kind which would never be used in therapeutic practice because it was desired in the first instance to obtain some recognizable effect. With therapeutic doses it had not been possible to observe anything which could be regarded as significant. He understood from Dr Cammidge that with the animal still fasting the blood sugar returned to normal (Dr CANNING Yes). Dr Dale said that that was a point he had not been sure about. He added on the general discussion, that it was very gratifying to find clinical results coming up to the expectations derived from physiological experiment.

## TRAUMATIC NEURASTHENIA AND THE "LITIGATION NEUROSIS"

A COMBINED meeting of the Section of Neurology of the Royal Society of Medicine and the Medico-Legal Society was held on December 8th, when Sir FARQUHAR BURNARD opened a discussion on traumatic neurasthenia and the litigation neurosis. It included an interesting digression by the Rt Hon H P MACMILLAN, K C, chairman of the recent Royal Commission on Lunacy and Mental Disorder, on the subject of the expert witness Professor LAWRENCE PRINCEWILL and, later, Dr GORDON HOLMES presided.

Sir FARQUHAR BURNARD said that "traumatic neurasthenia" was a term applied to a clinical condition familiar to both the medical and legal professions. It had led to much confusion, and until its etiology and pathology were clearly recognized and generally accepted the confusion was likely to continue. He submitted that traumatic neurasthenia had a psychopathological basis. Generally it developed slowly after an injury, the site of which was of no consequence, it rarely supervened on an injury which had caused grave physical disability, or on an injury the responsibility for which could not be placed on the shoulders of some person or persons other than the patient, and it was very rare apart from motor and railway accidents, workmen's compensation cases, and minor war injuries. He had seen three cases of this kind associated with a railway accident in which it was admitted that all the patients escaped without a scratch. It did not develop after such accidents as those of the hunting field, for which only the rider or his horse could possibly be responsible, the difficulty in such cases was to make the patient take his concussion or other injury seriously enough. The psychopathological features included fear (at the time of the injury), anxiety as to possible consequences to health, with a subconscious desire to safeguard the future in that respect, a sense of injury, ignorant interpretation of symptoms which arose as the neurosis developed, injudicious remarks and advice of doctors, relatives, and friends, and the worry of litigation. When the nature of the accident was such as to cause an emotional disturbance in the form of fear, this condition was, unfortunately, not referred to under its proper name, but as "shock." Recently the speaker had seen a woman who had been in a railway accident. She carried with her an illustrated paper with photographs of the wrecked train, in order that, although she had escaped unhurt, she and others might not underestimate the horrors of her adventure. For the first week she was exhilarated, and then followed an emotional reaction to which had been attached the unfortunate designation of "delayed shock." From that moment the question of compensation arose in her mind, with the result that the familiar picture of traumatic—or in this case, non-traumatic—neurasthenia was established. In workmen's compensation cases the contributory factors were often trivial separately, but their cumulative effect was overpowering, and the condition of anxiety neurosis was soon well established. To the lay mind trauma was still the most important and universal etiological factor in medicine. A pain here or there was sufficient to keep a person alert or complications or sequels, fear and anxiety robbed him of sleep, and so the vicious circle was formed. Was this condition to be regarded legally as the result of the accident? That some doubt was felt in juridical minds was evident from a letter which he quoted from a firm of lawyers in a compensation case.

"The employer's case is that the man's inability to work is caused by brooding over the effects of the accident and that he is suffering from weakness of will and a fixed but erroneous idea that he is a chronic invalid. If they establish this proposition the court could refuse further compensation. If, on the other hand, this man is suffering from neurasthenia as we are advised, he is entitled to a continuance of the compensation."

The problem was an important one from both the economic and ethical points of view. Its solution did not rest entirely with lawyers. If medical practitioners were as much alive to the psychological as to the physical dangers of a patient who had been in a railway or other accident, it they took as much care to prevent

infection of his mind with insidious morbid ideas as they did to prevent infection of his body with pathological organisms, many of these cases would be cleared up. The medical profession was to blame for using the term "traumatic neurasthenia" as denoting some disease which was the direct result of injury, and for talking about "shock" when what was really meant was "fright", still more reprehensible was the practice of treating a patient with established neurasthenia by giving him a weekly bottle of medicine and the exhortation to take plenty of exercise in the open air. Improvements in the standards of medical treatment, both preventive and remedial, would certainly lessen the incidence of traumatic neurasthenia, though they would not abolish it. Even if it were practicable to alter the law for dealing with these difficult cases, the matter of diagnosis would still give rise to perplexity, and the time-honoured but painful conflict of medical testimony would only be shifted to another field.

The Right Hon H P MACMILLAN, K C, said that this kind of problem was a familiar one, the judge had to discriminate daily between things which were and those which were not the direct consequences of the original wrong, or tort, or accident. The doctrine of remoteness came in, and not everything that followed an injury was treated by the law as a consequence of the injury which entitled the victim to recover damages for that sequel. But in the case of a railway accident, for example, it was legitimate to estimate the damages with regard to the supervening psychological state. The patient might have suffered no direct physical injury, but a pathological state of mind had supervened which would not have supervened but for the occurrence. Was this state of mind a matter for compensation? The law was not an exact science like medicine, criteria which might not commend themselves scientifically had to be applied. A criterion employed in the courts was that no person could recover in respect of a breach of contract or a tort (an injury) unless he could show that the consequences upon which his complaint was founded were the natural and probable consequences of the occurrence. Such a criterion was easy to formulate, but often difficult to apply, as in the case of a person injured in a railway accident who happened to be of a highly nervous temperament. The railway company must take its passengers as it found them. If some susceptible person were injured, so that the consequences in his case were graver than they would be in a person more temperamentally robust, that was the railway company's responsibility. Nevertheless, the law recognized what was called a *novus actus interveniens*, and if it could be shown that the condition of the patient was due, not to the occurrence, but to the patient having done something subsequently which had introduced into the chain of causation a new element for which the railway company was not responsible, then the law would say that the consequences were not directly and naturally attributable to what the company had done. The mere fact, however, that the patient was of a highly nervous type, with a disposition to brood or to magnify grievances, would not necessarily introduce a few factors absolving the company.

Mr Macmillan then discussed the function of medical practitioners in assisting the court to determine whether the symptoms exhibited by a plaintiff were the probable consequences of the occurrence, and said that they could make an invaluable contribution to the cause of justice. The expert witness, in spite of the gibes at him, was indispensable, and of all expert witnesses the medical practitioner was perhaps the most conspicuous in the service he was able to render to the administration of justice. Why was it that in certain types of actions the law had admitted a kind of evidence—evidence of the nature of opinion and inference—which it strictly ruled out in other actions? It was because the judge was not himself competent to draw the inferences. The expert witness was needed in order to illuminate with his scientific knowledge facts which would otherwise be meaningless. Courts of justice had enlisted expert assistance in three ways: by the use of an assessor, as in Admiralty cases, by appointing an expert referee, and by calling an expert witness, whose value depended entirely upon his attitude. The vice of the situation, not applicable to the

medical profession alone, was that there had grown up a wrong theory that the expert witness was in a sense an advocate of the scandal—it was a scandal—which had arisen over the conflict of medical testimony, not from a misconception as to the part which the expert played in court. The speaker had sometimes witnessed the struggles of an expert witness of the advocate type, trying to maintain an untenable scientific position. The function of an advocate should be left to the legal profession. The doctor was not entitled to distort the views he had expressed in the witness box, whereas the lawyer was not bound by what he had argued at the bar. The function of the witness was to assist the court by stating to the best of his ability the scientific position as he conceived it, without colour or favour.

In conclusion, Mr Macmillan said that probably the medical and the legal points of view would never be wholly reconciled, though some progress was being made in law, and cognizance was being taken of finer shades of differentiation, but the medical view remained necessarily scientific and exact, while the legal view was neither. He was not sure that it would be right to delegate to a body of medical men not subject to cross-examination, the function of determining whether or not the state of a plaintiff was attributable to the accident. The law had to take the standard of the jury in these matters. The conflict was between rough justice on the one hand and unmerciful refinements on the other. The law had learned from medicine to discriminate with more justice, but it would never overtake medicine in the precision with which certain questions could be determined nevertheless he thought such questions should be determined by a court of law, with the assistance of expert testimony.

Sir James PRAVIER STEWART said that traumatic neurasthenia was a genuine medical illness, whereas "litigation neurosis" was a legal complaint in the courts, the two conditions shrank into one another, and it required much skill to disentangle them. Litigation neurosis might be compared to a drink originally innocuous to which various exciting ingredients were added, so that it became a rather expensive and uncertain cocktail. The purely medical aspects of illnesses which became the subject of litigation would be a simple affair were it not for the element of compensation. The Workmen's Compensation Act had had widespread beneficial effects protecting the injured workman against the careless, unscrupulous or selfish employer, but one could not help thinking that it contemplated in the main the gross physical accidents arising out of employment. Nervous symptoms following accidents might be recognized as of two classes: those due to the expectation of financial solatium, and those due to actual physical injury. The patient's family and friends his solicitor also heightened the symptoms and thus the original condition was elaborated, decorated and intensified. The manufacture of symptoms if conscious was branded as malingering but much more commonly it was an unconscious affair. The injury afforded the patient a temporary freedom from work. His accident evoked sympathy and discussion with his family, friends, and solicitor fostered resentment. In a series of 17 compensation cases he had tried to obtain information as to what happened after the settlement. In 10 of them no medical particulars could be traced subsequent to the verdict of the jury; the remaining 7 had promptly recovered and gone back to work. In some of these cases large sums—up to £1,000 or more—had been awarded. Even the loss of his claim sometimes had a beneficial effect on the patient if he knew that it was final. A pension as a solatium was less advantageous for both parties than a lump sum for the pensioner tended to aggravate and maintain his symptoms in order to "earn" his pension.

Dr RUSSELL PERELL said that in cases where there was no question of litigation he had found precisely the same factors at work to produce neurasthenia. One of the provocative factors leading to litigation was sometimes the attitude of the medical practitioner representing the company who had been known to display incredulity and braggadocio and—on the other hand—what almost amounted to brutality. The company on the other hand, in the most gracious way, but an unkind attitude on the part of the medical man appear-

ing for the company not only aroused fear in the patient, who suspected that an effort was being made to defeat him, but also roused the antagonism of the patient's doctor, who set out to protect his patient, and thus all the elements of a litigious quarrel were introduced. People injured in the hunting field who did not develop these symptoms were those who could afford to be ill, but when a man was earning a small wage and had a family to maintain the prospect of being set aside for many weeks contributed greatly to his anxiety. There was no need to assume malingering. In many cases litigation might have been prevented by proper consultation beforehand between the medical men on the two sides. He had frequently been consulted by employers, but although in a sense on the opposite side, he conducted his examination of the patient and discussed the matter with his doctor in such a way that agreement was often arrived at without going into court.

Dr W. A. BREND, speaking from the point of view of a medical referee attached to three county courts, said that there had been a very marked decline in recent years in the number of cases coming into court. Two considerations seemed to help parties to come to a compromise: a belief that the case was settled quickly the applicant was more likely to recover quickly, and also the great uncertainty as to how the case might result in court. He thought the question of tremors and reflexes very important.

Dr W. SULLIVANT STURGE said that it was a commonplace during the war that the graver injuries were rarely followed by shock of any kind. Most of the neuroses following injury were in fact effects of fear. The worst case of so-called shell shock he had seen was that of a man who had been for nearly ten years wholly incapacitated by a purely functional paralysis, and yet who had been at no time nearer the war than Plymouth. Another patient incapacitated for life, was a fireman on an engine which nearly came into collision with another engine but in fact did not. There was no injury, but severe fright.

Sir WILLIAM WILCOX agreed with Mr Macmillan's view that the final decision in these cases ought to be left to judge and jury for the result would be a more commonsense and practical decision than one which emanated from a body of experts, medical or legal, but the best expert evidence should be available to assist the court.

Sir FARQUHAR BRIZZARD said that he had not had an answer to his question. Where a certain train of events chiefly psychological in nature, followed an accident, whose was the responsibility?

Mr MACMILLAN, in reply, said that he had been interested in what had been said about the curative effect of a verdict. It was not possible for any lawyer to answer categorically the question put to him by Sir Farquhar Brizzard. All that the law could do was to proceed on the best evidence it could get and so it threw the ball back to the medical profession. He suggested that there was no true distinction between a psychological and a physical injury because he rather understood that the psycho-pathological state would be found to be associated with some form of organic lesion and he had indeed on the basis of what he had heard in evidence committed himself to a statement of that kind in the report of the Royal Commission on Lunacy.

## FRACTURES OF THE SPINE

A MEETING of the Section of Orthopaedics of the Royal Society of Medicine was held on December 6th with Mr W. ROWLEY BRISTOW the president in the chair for a discussion on fractures of the spine.

Mr GEOFFREY JEFFERSON (Manchester) speaking first of the ordinary compression fracture drew attention to the effect upon the spinal column of hard injury. If the skull was struck by a hard body or moderately high velocity the almost certain result was fracture of the skull but in the injuring body was soft and yet heavy like a axe, the skull would probably escape injury and the full effect would be felt upon the spine itself. It was possible for a force to be so adjusted that it would be unable to overcome the resistance of the skull but overcoming that of the spinal column. The force might vary in weight

duction, and point of contact, and to this had to be added a very common thing in vertebral injury—namely, the movement in an oblique direction of the force itself, or of the vertebral column under the influence of the force. In the vertebral column there were two structures, one of them anterior, consisting of the vertebral bodies, and the other posterior, of the pedicles and laminae, and the former was much more easily collapsible than the latter. The speaker then went on to show statistics regarding injuries of the vertebral column treated at the Salford Royal Hospital from 1919 to 1927. The total number of such cases, not including fractures of the spinous and transverse processes, was 85, in 67 of which the level of the vertebral injury had been accurately localized. In 34 the injury was in the cervical vertebrae, in 13 in the thoracic, and in 20 in the lumbar. These cases, as well as 2,000 cases from literature, showed that there were two outstanding peaks of incidence, one in the lower cervical region, at the fifth and sixth vertebrae, and the other at the twelfth thoracic and first lumbar. These two groups of injuries were the result of entirely different causes. Practically the whole of the cervical ones were due to head injuries, while the others were caused by flexion fracture of the spine itself, particularly from such accidents as falling on the nape of the neck or on the shoulders. It was very difficult to produce fracture in the middle of the thoracic spine by compression, and the incidence of such injuries was very low. The cervical portion above and the lumbar portion below were the main sites of injury. After mentioning other points regarding anatomical structure and the mechanism of injury, Mr. Jefferson concluded with a word about treatment. The ideal which surgeons had in view, he said, was always reduction, whether obtained simply by manipulation or by an open operation, but he was doubtful as to the value of the latter in very many cases. Of the 18 patients who died in the Salford series just quoted, 16 died within the first week after injury, and none of them would have been saved by open operation.

Dr. GEORGE RIDDIOCH advanced some considerations from the neurological standpoint. The clinical course of a severe spinal injury, he said, might be divided into three stages. In the first stage there was acute paralysis and muscular flaccidity, with great diminution of reflexes and retention of urine—a more or less complete physiological block. Part of this disturbance of function was due to quite transient causes, such as oedema, and perhaps haemorrhage, and part was the result possibly of permanent structural defect. For many years it was looked upon as axiomatic that if the spinal cord was transected completely and permanent abolition of reflex function became evident, but this had been shown to be fallacious by the experience of the war. It was true that it held good in certain complicated cases, but in uncomplicated cases reflex function, even after transection of the spinal cord, began to return within a week or fortnight of the injury. Usually the first manifestation of it was an alteration in plantar response. About three weeks after the injury the tendon reflexes began to return—first of all ankle-jerks, then knee-jerks—and the retention of urine was no longer complete. These reflex activities gradually became more vigorous, especially the flexor reactions of the lower limbs. This was the second stage. It was clear that, although the cord might be completely transected the reflex activities could return. Patients with completely transected spinal cord might live for a considerable time. There was one case in literature of a woman who broke her back twenty-five years before and was still living. The longest case which had come under his own observation dated back for eleven years, to a war injury. The man was still active and went to his business. But too many such cases developed bladder sepsis and other conditions, such as pneumonia, so that a third stage was reached in which there were regressive changes, mirroring in the backward direction the improvements noticed in the second stage. The bladder, after having returned to more or less regular function, once more returned to the urine, and finally perhaps, before death took place, all the patient's reflex activities were abolished. The indications for operation in spinal injuries were few, and it had to be realized, in the first place, that the main

damage was immediate and irreparable in so far as anatomical change was present, and that it was impossible, during the period of spinal shock, to determine how much damage was due to such structural alteration and how much to a transient disturbance. No operation ought to be undertaken in any circumstances until the period of spinal shock was over—that is to say, from two to six weeks after the injury itself.

Dr. BERTHA SHINES continued the discussion from the standpoint of the radiologist. He believed that injuries of the spine were not sufficiently studied radiographically, but the method, especially with the use of stereoscopy, was capable of very great refinements. For example, he believed subluxation of the vertebrae to occur and to be discernible by efficient x-ray stereoscopy. The antero-posterior x-ray view of the upper cervical spine could be obtained only through the mouth, and this was not as easy as it appeared, on account of the different shape of the occiput in different persons. The x-ray diagnosis of fractures of the transverse processes, especially in the lumbar region, was rather difficult because of conflicting shadows of muscles and intestinal contents, only by careful stereoscopic radiography, again, could one be sure of the appearance. In fractures of the coccyx the lateral view was the important one. Fractures that caused encroachment on the spinal cord revealed themselves without the aid of lipiodol.

Mr. GEORGE STUBBING gave an analysis of the cases of fracture of the spine received recently at Lambeth Poor Law hospital. The number of cases was increasing rapidly. During the three years 1919-21 there were five cases, in 1922-24 twelve cases, and in 1925-27 thirty-two cases. This was due to the increasing frequency of street accidents, many such cases finding their way into a Poor Law hospital, especially if they were of such a nature as to require long institutional treatment. But spinal injuries appeared to be increasing at a greater rate than injuries to the limbs. Of the thirty-two cases received during the last three years, fourteen had gross injury, and five died in hospital. The date of death was, in general, a few days after the injury, but in one exceptional case a man died many years after his injury, a fracture of the dorsal spine which he had sustained at the age of 11. He had had a spastic paraplegia, but had been able to get about on crutches and even his living as a hawker. He died of pyelonephritis, which was the cause of death in all the cases of any long standing. Only a minority of the fractures were associated with gross nervous lesions, and those cases in which such symptoms were absent were still very commonly not diagnosed early, or, if diagnosed, were not treated by prolonged immobilization, which was the best treatment. Decompression operations had not proved to be of any value in this series.

Mr. T. H. OPENSHAW agreed with the last speaker that most of these cases died of pyelonephritis, also that long immobilization of the spine was essential for the recovery of many of these fractures. There were many cases of injury to the spine which had practically no nervous symptoms, and those were cases with which it was very important that the orthopaedic surgeon should be familiar, because they were liable to get into the hands of bone-setters, and to do the profession a great deal of injury. In one series of cases, having seen four deaths in patients with definite compression paraplegia, which had all the symptoms pointing to the cord being cut across, he determined to save if possible a fifth man similarly injured, and accordingly performed an operation which involved the wiring of about five of the vertebrae together, and the man recovered.

Mr. Sr. J. D. BURNETT reviewed a small number of cases which he had had the opportunity of investigating during the last five years. They numbered 29, 17 patients died, the last five years. They numbered 29, 17 patients died, 7 of them immediately, 11 survived and were well, and one other was unlikely to live. In nine cases the site of injury was at the fifth and sixth cervical vertebrae and in seven in the region of the tenth to the twelfth dorsal, so that his figures, although so small, bore out those of Mr. Jefferson as to the two principal peaks of incidence.

Mr. JOHN EVERIDGE raised the question as to what should be done with regard to bladder infection. In the cases of spinal injury there was at first retention of urine, which later passed on to retention with overflow, and

after a variable period a cessation of periodic micturition was brought about. In fact, the bladder in the later stages had the condition which one associated with children up to about the age of two years. If patients could only be bled over this period without infection there might be some hope. He wondered whether early suprapubic cystotomy, to be carried out as soon after the injury as possible, was to be recommended as a procedure not only for combating but for preventing infection.

Mr P. B. BORN described a case at the Miller Hospital, following in which Mr. Leidecke had just stated in which, after consultation with his colleagues, it had been decided on the narrow to do a suprapubic cystotomy. It was an interesting question whether in this operation were carried out a day or two after the injury cystitis would be prevented. Dr J. F. BRIDGES showed a large number of x-ray pictures illustrating the appearances in various conditions of spinal injury.

### OPERATION FOR PAPILLOMA VESICAE

At the first meeting of the Midland Obstetrical and Gynaecological Society at the Medical Institute Birmingham on November 8th the President Professor D. L. RYAN, in the chair Mr CHRISTOPHER MARTIN (Birmingham) read a paper on the operative treatment of papilloma of the urinary bladder.

Mr MARTIN said that papilloma of the bladder occurred much more often in men than in women and was easily recognized by the sudden onset of haematuria which rapidly increased in severity by the finding of papilloma fragments in the urine and by cystoscopic examination. In the operative treatment the bladder was washed out with some non-toxic antiseptic, such as iodine water, and filled with from 10 to 20 ounces of the same solution. The patient was now put into the Trendelenburg position at about an angle of 45 degrees and the abdomen was opened by an incision in the middle line extending from the middle of the pubes upwards for about four inches when the anterior surface of the bladder protruded into the wound. Two temporary silk traction sutures were passed with a curved needle through the muscular wall of the bladder about an inch apart one on each side of the middle line, and the bladder was opened with a sharp scalpel by a mesial incision from two to three inches long. As soon as the lotion distending the bladder had escaped it was advisable to put two other silk sutures through the cut edges of the mucous membrane to act as additional tractor. The interior of the bladder was wiped dry with soft gauze pads care being taken not to bruise the growths and start bleeding the cavity was carefully inspected with a good light and the position of the growth or growths determined. A tubular metal speculum three and a half inches long and an inch and a half in diameter was passed into the bladder through the wound and the growth made to project into its lower opening. This speculum was of great service in isolating the growth, in keeping the field of operation nearly dry and in protecting the abdominal wound from contact with the cavity. The base of the papillomatous growth was then seized with a stout pair of curved artery forceps at the point where it sprang from the mucosa, and was crushed by closing the forceps firmly. With scissors or Piquet's cautery the growth was cut or burned away close to the upper surface of the forceps and the cautery point heated to a dull redness passed to and fro over the charred stump if this was done slowly and deliberately there would be no subsequent haemorrhage. The forceps were cautiously loosened and if haemorrhage restarted the pedicle was cauterized again. When the forceps were removed the pedicle should be a thin bloodless horny ridge almost flush with the mucosa. With multiple growths the same procedure was followed with each in turn until they were all completely burned away. The whole of the interior of the bladder was now carefully inspected and any small growths isolated with the speculum and burned out, for such papillomata—no larger perhaps than a pin's head—the fine needle point of the cautery was very useful. The bladder was then gently wiped out with soft gauze swabs care being taken not to start bleeding by roughly rubbing the charred tumour

basis. The silk traction sutures were removed, and the wound in the bladder was closed without drainage from below upwards with a continuous suture of fine catgut. It was important not to pass the stitch through the mucous membrane. The line of continuous suture was usually strengthened by three or four interrupted mattress sutures. A "cigarette" drain was passed through the lower part of the abdominal wound into the cellular space between the bladder and pubes, it was removed in about forty-eight hours. A glass self-retaining catheter about three inches long was inserted into the bladder through the urethra. The upper slightly bulbous end lay just above the pubis and the lower flanged end outside the natus. A short rubber tube passed from it to a urinary in the bed laid between the patient's thighs. This glass catheter was removed every twelve hours and a freshly sterilized one inserted. This continuous drainage of the bladder was maintained for ten or twelve days after the operation. The abdominal silk sutures were removed on the twelfth day and the patient allowed to sit up if all was well on the fifteenth day. During this fortnight the diet must be light and non-stimulating with plenty of bland diluent fluids such as barley water.

### Degeneration Changes in Fibroids

Mr FURNEAUX JORDAN read the notes of four cases of fibroids undergoing degeneration and exhibited specimens of two of them.

The first was a patient aged 53 from whom the late Proctor Taylor had removed the ovaries for a large fibroid in 1912. She came to Mr Jordan in 1917 with a history of five years amenorrhoea but no diminution in the size of the tumour and lately there had been attacks of acute pain in the abdomen and a slight blood-stained discharge. The uterus was removed and the fibroid was undergoing red degeneration.

From the second patient who was 43 years old both appendages had been removed in 1912 for a left tubal pregnancy and a cystoma of the right ovary. Five weeks before the date of her meeting he had been seized with pain in the back, creeling round to the front of the lower abdomen and causing pain on micturition with frequency. A fibroid was found two weeks later completely filling the pelvis and rising half way to the umbilicus. For three and a half months she had menorrhagia too often each period lasting for two weeks and accompanied by bearing down pain. The tumour was removed by subtotal hysterectomy and very deep adhesions were found on the left side of the site of the previous tubal gestation. The fibroid was large, lobulated and was beginning to undergo sloughing on the surface. The patient was making a good recovery.

The third patient aged 62 was single, the menopause had occurred at 51 for many years but she had felt a weight inside her and always tired easily three years ago. Very troublesome frequency of micturition had tarred and was now getting progressively worse. The pelvis was filled by the second stage of labour which ennobled the pelvic head in the second stage of labour. During hysterectomy the uterus was found to be a thin shell stretched over an old fibroid which had become calcareous. It had probably become wedged in the pelvis recently. The patient had regained very good health.

The fourth patient aged 67 had had no children and had suffered from rheumatoid arthritis for many years. Twenty-five years previously the ovaries had been removed for fibroid tumours of the uterus. For three months she had had a discharge white at first but for over a month blood-stained for three months pain had persisted in the lower abdomen. There was a hard rounded tender mass about the size of an apple in the uterus. Hysterectomy was performed and developed universal dense adhesion coils of intestine matted together and growing from the uterus into the right broad ligament and a fibroid calcified on the surface but not in the interior. The patient had made a good recovery.

Mr Furneaux Jordan said the cases showed that fibroids, even after the menopause whether natural or produced artificially might even further trouble by undergoing degeneration. He doubted whether this contingency was sufficiently remembered when patients were advised to wait until the menopause had occurred. It was possible that in the first two cases and almost certain in the second one the ovaries were not removed in their entirety. It would be a matter for subsequent observation whether cases of fibroid treated by deep x-ray therapy with the symptoms completely arrested would not later on, be liable to undergo degenerative changes.

### Obscure Coital Growth

Miss HILDA SHUFFLEBOTHAM (Birmingham) showed a case for diagnosis.

An unmarried woman aged 33 had had a history of rufles at the age of 3 months followed by a nodule when she was old. She had been treated for scabies but the

Wassermann reaction was still positive. The mother was syphilitic and the father had died from general paralysis at the age of 28. In May, 1927, the patient had been prevented from working by a pain in her left side. Four months later she noticed two swellings on the chest wall, tuberculosis of the ribs was eventually excluded by negative x-ray findings. She also suffered from frequent vomiting, pain in left side, general malaise, and depression. The two large swellings on the left side of the chest were about the same level, one was near the anterior border of the axilla just below the breast, the other just behind the posterior border of the axilla. They were apparently attached to the ribs and partially cystic, with indurated tissues around. They were tender, and hot, but there was no redness of the skin, nor were they attached to it. The x-ray examination showed some slight involvement of the ribs, but no abnormal lung condition was present, the swellings were entirely outside the thorax. About 40 ccm of practically clear yellow fluid was withdrawn from the anterior swelling. No tubercle bacilli and no definite tumour cells were found, but there was a predominance of polymorphonuclears. Both swellings were completely aspirated and each was injected. The ribs were found to be tender on pressure after aspiration. The blood count showed diminution in the red cells and an increased percentage of large lymphocytes. A second x-ray examination showed much more marked involvement of the eleventh and twelfth ribs, with complete bone absorption, and involvement of the lower border of the tenth rib.

Miss Shuffelebottom said that the differential diagnosis lay between (1) syphilitic periostitis of the tenth, eleventh, and twelfth ribs, with localized collections of fluid, (2) sarcoma of ribs, and (3) tuberculous periostitis of the ribs. The history and physical signs seemed to point to the first diagnosis as being correct.

#### *Echinococcal Cyst of Pelvis*

Mr ALFRED B. DUNN described a case of a primary extraperitoneal echinococcal cyst of the pelvis.

A healthy female child, aged 6, had suffered from five attacks of acute retention of urine during the preceding four months and on each occasion catheterization was necessary. A median hypogastric swelling reaching half way to the umbilicus was found. It was punctured by catheterization, and was continuous with a large cystic swelling in the pouch of Douglas occupying most of the pelvic cavity. A diagnosis was made of an impacted ovarian cyst, probably dermoid. At an operation the bladder was found displaced upwards several inches above the symphysis pubis, and behind it was a tense cystic swelling the size of a foetal head which occupied the pouch of Douglas was retroperitoneal, and appeared to distend the layers of the broad ligament. The abdomen being carefully packed off, a small incision was made into the swelling, a trocar inserted, and slightly opalescent fluid drained off which was found to contain the characteristic hooklets. On enlarging the opening the cyst was completely shelled out and the typically translucent elastic wall of the endocyst was recognized. The abdominal contents were inspected, including the liver, but only a small rudimentary cyst barely 1/2 in by 1/4 in attached to the distal free end of the great omentum was found, this was removed. Great care was taken over the peritoneal toilet, the retroperitoneal cavity was packed with iodoform gauze and a rubber tube was inserted. No signs of further infection had appeared subsequently.

Mr DUNN said that the specimen showed the ectocyst and endocyst clearly, but there was no sign of formation of daughter cysts, which in the opinion of Sir Alexander MacCormick were only formed after rupture of the cyst wall of the parent hydatid. The cyst appeared to have arisen from the cellular tissues at the base of the broad ligament, but how the embryo invaded these tissues must be largely a matter of conjecture. The early recognition of the cyst could be explained by its causing urgent urinary symptoms. Examination of the blood showed no eosinophilia. No other cases had been reported in the same district and there was no history of eating water-cress or keeping pet animals.

#### TREATMENT OF RAYNAUD'S DISEASE

At a meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland on November 25th the president, Dr G. E. NEWMAN showed jointly with Mr A. V. McCONNELL a case of rather severe Raynaud's disease treated surgically in a woman who had suffered for six years.

The patient's hands were almost constantly cold blue and stiff and the skin about the nails of the right hand frequently threatened to break down. She had been compelled to abandon her occupation of nursing in consequence. On November 8th Mr McCONNELL had performed a sympathectomy by injection of alcohol into the sheath of the right brachial plexus. Immediate improvement had been noticed in the condition of the right hand, which became pink in colour, the hardness and stiffness disappeared and the patient could now use her fingers even for fine work with comfort.

Mr McCONNELL said that although the immediate effect had been quite satisfactory these cases were liable to relapse, and that permanent cure could scarcely be expected from this method of treatment.

Sir WILLIAM WHEELER said that he had performed the operation of sympathectomy on many occasions, but in true Raynaud's disease and in thrombo-angitis obliterans he met with no marked success. Vaso-dilatation occurred below the site of operation, and the temperature of the part was materially raised. In impending gangrene, certain cases of embolism, and in intractable ulcers, the operation was followed by good permanent results. In true Raynaud's disease of the lower extremities Adson and others had obtained success by combining the operation of sympathectomy with removal of the lower lumbar sympathetic ganglia. Sir William Wheeler had tried Simpson-Hurdley's method twice, he believed it produced the desired effect, but he did not find it more simple to perform than the removal of the sympathetic plexus with the adventitious internal sheath. The operation was followed by remarkably quick healing in refractory ulceration and torpid wounds, one of the most striking sequelae being the relief of the pain which was associated with vascular disturbances in the extremities, this occurred even in Raynaud's disease and in thrombo-angitis obliterans, which otherwise were not benefited. Pruning the segment of the vessel with phenol had recently been suggested as an alternative to Simpson-Hurdley's method.

Dr L. ABRAHAMSON stated that in one case of Raynaud's disease no permanent good result had been obtained, and there had not been relief of pain after the operation.

Mr W. PEARSON said he had often performed this operation during the war, but so far as nerve conditions were concerned he had found it useless, and had abandoned it, he had not tried it for Raynaud's disease. He referred to a case of frost-bite in the feet with gangrenous ulceration, and almost perpetual vesication of the dorsum in both feet, which sometimes broke down into superficial ulcers, after the operation the patient had recovered completely. In a man aged 70 with symptoms of intermittent claudication in the right leg the pain had been greatly relieved since operation.

#### *Propulsion Through the Colon*

Dr C. L. McDONOUGH read a short note on the movement of the contents in the large intestine, and showed illustrative radiograms. The importance of "mass movement" in the passage of material through the transverse and descending colon was emphasized, and the stages of this movement clearly shown by radiograms from the author's cases.

Dr M. R. J. HARRIS said that it was due to the investigations of Cannon and others in America that so much was now known about the movement of the intestinal contents. Formerly it had been thought that the movement in the colon had an onward direction, now it was known that there were two varieties, a pendulum and an onward propulsive movement. When the contents of the colon entered the rectum there was a desire to empty this part of the bowel. If this desire was neglected the rectum enlarged, and the desire to defecate passed away till the next day. This had been described as dyschezia. He did not think that this fact was appreciated by those who had not recently studied physiology.

The PRESIDENT thought that neglect to respond to the stimulus of the rectum was responsible for most cases of constipation.

#### JAMES MACKENZIE INSTITUTE

On November 15th Dr EDWIN MATTHEW read a paper on the clinical significance of haematemesis. He first enumerated the conditions in which haematemesis might occur, and pointed out that it might be present in certain blood conditions associated with high blood pressure, or from a variety of other inner causes. He quoted statistics derived from the clinical material in his own wards in the Royal Infirmary, Edinburgh, which went to prove that in the diagnosis of chronic gastric ulcer, especially when other signs and symptoms were indefinite or atypical, haema-

tumescence was an all important factor in the diagnosis. In his experience haematemesis in duodenal ulcer tended to be more severe and more prone to prove fatal than in gastric ulcer. A large, sudden haematemesis might, however, be associated with acute gastric ulcer, high blood pressure, and also might occur in splenic anaemia, rendering differential diagnosis difficult. Haematemesis, especially if repeated, offered an indication for surgical treatment in chronic gastric and duodenal ulcer, and in splenic anaemia, in which splenectomy might be performed with cessation of haematemesis.

## Reviews.

### THE NEUROTIC PERSONALITY

Dr R C Gordon, honorary secretary of a special Psycho-analysis Committee appointed by the British Medical Association and the author of *Personality in the International Library of Psychology*, reviewed in our columns in June, 1926 (p. 949), has now written *The Neurotic Personality*. This is of a more general character, and addressed not so much to the specialists as to the rank and file of the profession and even to the general public, who, he considers, should also appreciate the vagaries of the neurotic. In the first chapter, on the construction of personality, the influence of the internal secretions is considered and it is pointed out that the anterior lobe of the pituitary, which milks for masculinity may be responsible for conflicts between femininity and masculinity in a woman with anterior hyperpituitarism. Dr Gordon agrees with Professor W McDougall that failure of integration within the self regarding sentiment is the characteristic mental lesion in neurotic states and that attempts at treatment should be directed to restoration of this integration.

The Freudian theory attributing neurosis to sex influences is discussed as is the Oedipus complex and without accepting these views appreciation is expressed of Freud's services to psychology. Among other conceptions of the neurosis Jung's view that they depend on inability of the individual to adapt himself to life as incompetence due to failure in psychic force is quoted as being singularly complete if the premisses on which the hypothesis is based could be established. Dr Gordon rather wickedly adds that the gist of Dr E D Adrian's contribution to the Psychological Congress in 1923 was that there is nothing except lack of the slightest evidence in its favour, to prevent the discussion of a special form of energy which differs from other forms as electricity does from heat. After accounts of the psychological types in neurosis the anxiety states, obsessions, hysteria, the dissociation syndromes, and exhaustion neurosis there is a well considered chapter on the physician and the neurotic individual in which emphasis is laid on the importance of a real understanding of the patient who is like a young and frightened horse dashing about in a field and trying to get out while all the time the gate through which the physician must lead him is open. But it must be realized that no one, however skilled, can succeed with every neurotic.

The part the physician should play in treatment the Freudian transference between them, and the risk to which the medical man may be exposed are all explained, and the subject of treatment is fully dealt with under the heads of the scope and limitations of psycho-analysis, suggestion and persuasion. The concluding chapter of this well written and open minded book deals with the relation of the patient to the public at large, and the attitude of the man in the street to the neurotic.

### CRIME AND CRIMINALS

The number of books on crime and criminals which are being published at the present time is very large even those that are sent to us are so numerous as to be embarrassing. We may, however, notice a book on Crime

and the Criminal by Dr PHILIP ARCHIBALD PARSONS, Professor of Applied Sociology in the University of Oregon because, though it is primarily concerned with the methods followed in the United States of America, it has considerable interest for British readers. Legal processes for the arrest, conviction, punishment and amendment of the criminal differ considerably in the two countries, but their aim is the same.

The criminal is a menace to life and happiness. He imposes financial burdens upon society and is himself an economic liability. He is a great obstacle in the way of social progress and is a striking example of social inefficiency. Society views him with a lingering fear, a fear which in special crises develops into terror and even hysterical manifestations. There is a cry for vengeance or a clamour of special pleading which may defeat the end of justice. The loss due to crime in the United States is estimated at five to six billion dollars a year and this estimate takes no account of loss due to "graft" nor of the costs of police, law courts, judges, juries or of penitentiaries. The modern criminal is not like his popular picture. Once two celebrated actors took the parts of Fagin and Bill Sikes in a stage version of *Oliver Twist* played in New York. The chief of Pinkertons, and later of the New York detective force was asked to see it and decide whether the actors were true to life. He reported that the play was fine but if the actors had stepped on to Broadway they would have been arrested on sight. "They looked too much like criminals. And present-day criminals don't." Lombroso was responsible for fixing a physical type in the public mind. His conclusions were wrong as has been conclusively shown by the work of Goring and Karl Pearson but he did good by initiating investigations. Goring's conclusions better meet the case—that criminals as a class are inferior human beings characterized chiefly by their stupidity and inability to play the game according to the rule of modern society.

Dr Parsons recognizes varieties of criminals thus: insane criminal, born criminal, habitual criminal, professional criminal, occasional criminal, the criminal by passion or accident. The tendency is to the belief that while mental deficiency is not in itself a primary cause of antisocial conduct under certain conditions it becomes a contributing factor in the product of conduct disorders. Whether or not crime has increased in incidence is a moot point our ideas of crime change. But there is evidence—so far at least as the English speaking peoples are concerned—that there is a modification in the violence and seriousness of criminal acts. The decrease Judge Holt of New York City says is the result of civic and social effort to eliminate the factors responsible for delinquency and neglect.

In cold countries crimes against property are, it appears, more prevalent than crimes against the person. Obscene acts rise from a minimum in cold January to a maximum more than double the minimum in warm July. Crimes against property reach their height in early winter. In many European countries statistics indicate that crimes against property—principally theft—rise and fall with the price of the principal cereal food. There is reason to believe that this correlation exists with a fair degree of regularity all over the world. Men who work for themselves have a much lower rate of criminality than those working for a wage. At the present time there is no evidence that the system of education has either increased or decreased crime. It has been pointed out with what frequency crime is preceded by truancy from school, itself a sign of individual maladjustment.

After dealing with the criminal and modern crimes Professor Parsons proceeds to consider the reaction of society to the criminal and discusses the police theories of punishment, reform of penal institutions, substitutes for imprisonment, the treatment of youthful offenders, and new conceptions and treatment of crime.

His review of trial by jury is of great interest. In this country there is no difficulty in getting a jury empanelled with order and speediness, it is otherwise in

*The Neurotic Personality*, By R C Gordon, M.D., D.Sc., FRCP, Ed. International Library of Psychology, Philosophy and Science, M. D. London: Hogarth and Trench, Trubner and Co., Ltd. 137 (D.M.) 8vo pp. x + 22. 10s. 6d. net.

*Crime and the Criminal*, In *Interpretation of Crime*, By Philip Archibald Parsons, Ph.D., New York and London: 1927. 11.11.1. 8vo pp. 226 (Ext. 12. 8vo pp. xvi + 257. 10s. 6d. net.)

the United States, where, on occasions, weeks have been wasted on this ritual procedure. "In 1920 two months were required in securing a jury, and 1,200 prospective jurors were examined." His criticism of the jury in sanity trials is particularly severe.

Perhaps there was some excuse for the use of the jury in passing on the sanity cases in the days when insanity was detected by the obvious depravity of an individual from what was considered to be a normal mental state. With the present development of the science of the mind and nervous system in health and disease, however, it is now a well known fact that the number of persons who reveal their mental pathology by conduct strikingly out of the ordinary is relatively small in proportion to those whose deviation from normal mental health is commonly detected only by the trained observer. Most of these would appear to the ordinary jury as normal individuals.

The author is disturbed by a sinister aspect of the present situation, in which an individual of good standing in the community discovers that he does not lose caste with his group by unsocial or antisocial behaviour.

The law is a crude device for restraining conduct. Only the stupid and impulsive, the poor, and the weak violate it. The clever and the rich can gratify their unsocial and antisocial desires to a great extent by extralegal means, or, in many instances, by open defiance of the law. Antisocial mobilizations of power, such as criminal political organizations, may be strong enough to afford members protection against the authority of the State.

This is a book which every magistrate might read with advantage, and will be a help to those who have to do with child delinquents. There is an excellent bibliography.

### OTOLARYNGOLOGY IN GENERAL PRACTICE

Dr. Crow describes his book on *The Ear, Nose, and Throat in General Practice* as an informal guide to the main principles, and thus dismisses criticism, for there is no attempt to present a complete, even though condensed, account. The author has selected certain aspects upon which he holds strong views, and considers that the mind of the practitioner needs to be enlightened on it in its entirety.

Although he touches upon other matters, the adequate treatment of acute otitis media, the prompt removal of foreign bodies from the ear and food passages, and the technique of operations for removal of adenoids and tonsils are those which chiefly engage his attention, and he also advocates a wise conservative policy towards the nose. The views expressed are sound and definite, and they relate to points about which many practitioners hesitated to pronounce. The author really produces that additional emphasis after which he evidently strives. In a volume of the same size a balanced review of the whole subject might have been presented by omitting many redundant illustrations and many pleonasmic in the text. The result is a book which is no colourless compilation, but full of character, and evidently based upon intense personal convictions, with the natural corollary that the outlook is limited.

### LIVING MACHINERY

*Living Machinery*, by Professor A. V. Hill, contains six lectures he delivered at the Royal Institution last Christmas. The book deals chiefly with the neuro-muscular mechanisms of the body, and especially with the laws governing the activity of the voluntary muscles. The mechanisms of cardiac and involuntary muscles, however, are considered also. The book is written in an interesting style, and shows that Professor Hill has a special gift for simple and lucid exposition. Although originally written for children, there are few adults who will not require much interesting new knowledge from its perusal. The last chapter entitled "Speed, strength, and endurance," has a particularly wide interest, for in it we considered the factors that govern the making of athletic

records. Endurance is shown to be due chiefly to the rate at which the heart can supply oxygen to the body and to the capacity of the body to run into oxygen debt. The author suggests that it would be an interesting experiment to construct a suitable tunnel and fill it with pure oxygen, to see if it is probable that under such conditions a champion would be able to run the mile in less than four minutes. Another point he makes is that ability to climb at high altitudes probably depends on the same factors as the necessity for success in long-distance running, he thinks, therefore, that the long-distance runner is the most likely type of person to succeed in climbing Mount Everest.

The book is full of examples of the way in which general physiological principles can be applied to practical problems. Anyone, indeed, who wishes to get a general idea of the latest recent advances in our knowledge concerning neuro-muscular mechanism will find this book very useful and interesting.

Unfortunately, functions of the body cannot be explained without assuming an elementary knowledge of physics and chemistry, and those who do not possess such knowledge may not always find it easy to follow Professor Hill's statements, although, as has been said, he writes in a remarkably simple and clear style. All, however, who have knowledge of elementary science will find the book both interesting and instructive.

### PLOUGH COURT

The history of any long established business must needs be interesting and in some cases romantic, and it is a pity that more have not been recorded. That of a great firm of chemists and druggists, such as Allen and Hanbury's, is of special interest to the medical profession, whose activities have been so closely connected with those of the druggist, some of its members have taken important parts in the management of that firm. In *Plough Court: The Story of a Notable Pharmacy, 1715-1927*, Mr. Ernest C. Cripps has drawn a pleasant picture of the doings of the forceful but fine character of the men who built up the business, Plough Court, Lombard Street, where Alexander Pope was born, his being the seat of this pharmacy ever since. Syllums Bevan, the Quaker descendant of Jenkins of Evesham, took a lease of No. 2 from Sir John Osgood in 1715, and added No. 3 to it soon afterwards. For 157 years the same premises were used, and for almost exactly the same period the partners in the firm belonged to the Society of Friends. In 1893 the business became a limited company, with members of the family of Hanbury on its board of directors.

Syllums Bevan, like a number of his successors, was more than a business man. He linked in his day is a man of science, and in such became a Fellow of the Royal Society, the first of five Fellows who were named in the Plough Court pharmacy, not counting Luke Howard, F.R.S., who was at one time a partner and the founder of a firm still celebrated for its quinine and many other products. Bevan, although he did not hold any diploma, seems to have practised as a physician, and was known as Dr. Bevan. His son, another Syllums, gave up pharmacy to join the Quaker banking house of Barclay and Co. The name of Allen first appeared in the style of the firm neglecting his business he became widely known as a pupil at Thomas's Hospital. He had been "physician's 1807. He was a friend of Sir Humphry Davy and ketmed at the Royal Institution. Like others of the Quaker partners in the firm, no consideration of profit would induce him to forsake his principles, and it does not seem that he lost thereby. In order to contribute even so little to discourage negro slavery he returned from the use of sugar—a slave-made product—for forty-three years. His partner, Barry, refused to supply drugs to a French mil-

*Plough Court: The Story of a Notable Pharmacy 1715-1927*, compiled by Ernest C. Cripps London Allen and Hanbury's Ltd 1927 (Med. 8vo, pp. xvi + 227 Illustrated 10s 6d) Medical practitioners 12s 17s 6d net one copy from Allen and Hanbury's at the reduced price of 5s 4d net

the hospital because he held that it was "professedly for the purpose of encouraging men to enter the army"

The name of Hambury first appeared in the firm when Daniel Bell Hambury and his brother Cornelius, nephews of William Allen, became partners in 1824. Daniel Bell's son, Daniel, rivaled in scientific repute his great uncle, William Allen. As a botanist and pharmacologist his fame was world wide. At present the medical cabinet of the firm is Mr. Reginald J. Son Hambury. Space does not permit further comment on the many interesting things in this book, which itself bears evidence of the widened interests of the company, for it has been printed and produced in the Bethnal Green factory. The descriptions of this factory and of that at Warr, where oink and milk preparations are made and of the over a branches and agencies in the Norwegian cod liver oil factories are all of interest. The book is well illustrated with portraits, views and facsimile letters, and we feel sure that many medical practitioners will avail themselves of the offer of one copy each at the less than half price of five shilling.

## NOTES ON BOOKS

THE eighty fourth annual issue of the *Medical Directory*\* for 1923 has been published this week by Messrs J and A Churchill. There are very few changes in it as compared with previous issues and the care taken in the compilation of the records of 53 289 members of the medical profession is as evident as heretofore. Whereas in each of the four previous years however the annual increase was over 1200 it is now noteworthy that the total has been increased this year by only 731 names, there being a decline in the sections devoted to Scotland and the Services. The increase in the number of names of medical practitioners in the Provinces is about the same as in previous years but London shows a sharp drop compared with 1927. Dr R Lortuesque Fox has again supplied a description of the past and climatic health resorts of Great Britain, Ireland and New Zealand; this covers thirty seven pages and it is conveniently arranged and well illustrated. At the end of the volume is a date list, including new names and recent changes of address. The present issue of the *Medical Directory* fully equals the best of its predecessors and a indispensable book of reference will return the favour it has won in the past.

In *The Game of Health* Dr J. MAXWELL TAYLOR sets out the principles of health education in the form of an analogy, and with a simplicity of language calculated to appeal to the older boys and girls of the elementary schools. The method adopted is well illustrated by the chapter headings—namely Games, The health team, The opposing team, The playing field. The strategy of the game<sup>1</sup> and the core emphasis is laid throughout on practical rather than theoretical aspects, and a considerable number of useful suggestions are attractively given. The analogy of Association football is not unduly strained, since the modified game used as an illustration of the contest between hygiene and disease is now very different from that played by children on public commons. The book may be recommended as having an immediate value for children and also as being likely to kindle in them an interest in the cultivation of health which in later years may lead to further study and more careful observation of its rules.

In *A Short Account of the Antiquity of Hindu Medicine*, Dr. David C. Mitter covers a period of 5600 years from 4000 B.C. the date of the Rig Veda, until A.D. 1600. The beginnings of civilization in India with which medicine was contemporaneous go back, as recent excavations in the Punjab and Sind amply prove much further than those of ancient Greece and it would appear that Greek and Arabian medicine was indebted to the Hindus and not that the Hippocratic teaching influenced the medicine of India. From 2,000 to 600 B.C. the Epic Period the Indo Aryans reached the zenith of their civilization and the standard works of Charaka and Susruta then produced were revised and reedited until A.D. 1500. In the Buddhist period (600 B.C. to A.D. 600) civilization began to decline and anatomy previously practised was discouraged but though surgery did not advance the study of chemistry and medicine did. One of the last great

men who threw lustre on Hindu medicine was Bhava Misra or Bharras (A.D. 1500), who is said to have anticipated Harvey in speaking of the circulation of the blood and to have prescribed mercury for syphilis.

*The South American Handbook* for 1928, the fifth year is a reminder of the importance of the great Latin American continent. Information on every topic is given in very readable and attractive form, and the print is never too small or indistinct. The steamship routes are set forth in detail whether by the eastern route to Buenos Aires with calls at Bahia Rio de Janeiro and Santos, all of them important ports of Brazil, or by the western route to Valparaiso through the Panama Canal with a call at Callao for Lima, the capital of Peru. The book contains one large coloured map of the continent, and many small sketch maps of particular areas. In the huge map the vast extent of Brazil is clearly shown, most of its area is indeed still unexplored. Portuguese is the prevailing language of civilization in Brazil, but some Indian dialects persist. Elsewhere from Venezuela in the north to Chile and Argentina the language is Spanish. The seasons are, of course, reversed and the South American summer is at its height in January. It may be noted that Buenos Aires, the capital of Argentina, actually lies further south than Capetown. The most striking trip the tourist can make is from Buenos Aires to Valparaiso across the continent from east to west, the journey can be broken at Mendoza, the garden of the Andes and continued through the mountains in view of the highest peak—Aconcagua, 23,000 feet (said to be the highest mountain of the Western Hemisphere). A steep descent leads to Valparaiso the chief seaport of Chile. The natural resources of all the different republics are described as also the habits and customs of the Indian tribes—for example the Araucanians or Chile particulars will be found too as to climate and as to currencies and costs of living. The book has been carefully prepared, and no pains have been spared to show the magnitude of Latin American contributions to the real wealth of the world.

## PREPARATIONS AND APPLIANCES

**A SIMPLE THERMO-TAT**  
**TRISTROY DAVIS** has devised a simple thermostat, the principle in construction of which is inexpensive in construction. A piece of glass tubing (a) bent as shown in the illustration contains mercury and a small drop (c) of a liquid which boils at the temperature desired. The inlet pipe (b) is drawn out to a point and may if desired have a by pass hole in it or a by pass may be arranged separately. The outlet is indicated at (c). A cork (d) is bored to take the tubing and is thoroughly impregnated with paraffin. If the tubes are warmed by a fire resembling them the apparatus is gas tight. The liquids used are ether for the incubation temperature of 35° C. acetone for the embedding bath of 50° C. and carbon bisulphide for the hot plate at 47° C. When carbon bisulphide is employed it should be well shaken with a little mercury before use this will prevent it blackening the mercury in the thermo-tat.

**RADIO-TOL.**

We have already mentioned on more than one occasion the preparation Radio tol manufactured and sold by the British Drug Houses. It is obtained by ultra violet radiation of ergosterol and is believed to be identical with the substance previously known as vitamin D. Undiluted radiotol possesses 200,000 times the activity of good cod liver oil—one sixth of an ounce being the equivalent of a ton of cod liver oil. It has hitherto been issued in an oily solution but the firm has now sent us samples of an improved method of dispensing the substance in a sugar-coated pellet into which has been incorporated a measured quantity of radiotol. A bottle of these pellets containing fifty can be obtained at the price of a cod liver oil. The existence of this preparation should facilitate antirachitic therapy since difficulty is occasioned with the pronounced taste of cod liver oil can now be avoided.

**THYROID TABLETS**  
Thyroxin, the active principle of the thyroid gland, is now issued by Burroughs Wellcome and Co. as Tablet Thyroxine in bottles of 100. Two strengths are available: 0.005 gm and 0.001 gm. The dose for adult is from 0.002 gm to 0.002 gm orally. Minimum doses should always be given at first and the optimum amount for each case should be determined by trial.

**DRIED LIVER**

Messrs. Allen and Hanbury Ltd inform us that they have prepared and are now in a position to supply liver in the form of a fine powder which is palatable and readily taken. 2 oz. of this product are rated to be equal in activity to 8 oz. of fresh liver. It is supplied in 1 oz., 2 oz., 4 oz. and 8 oz. bottles.

## FRACTURES OF THE SPINE

SEVERE injuries of the spinal column have long attracted the interest of surgeons and neurologists, but until recent years their incidence has been, generally speaking, confined to mining districts and those where what are called heavy industries are carried on. Formerly opportunities of studying these injuries were few in other places, but the great increase of fast and heavy motor traffic has made these—and, indeed, all manner of severe fractures—familiar to surgeons in most parts of the country, and particularly in places situated near the great cities and the main roads which lead to and from them. The effects of being hurled from a car travelling at high speed, or of being violently squeezed between two vehicles, are as damaging as those of a fall of roof in a colliery or of falls of the body from a height. Mr. George Stebbing's experience in only one London Poor Law hospital shows an alarming sixfold increase in the admissions of cases of fractured spine in the last decade. Whatever deductions from the totals may be necessary on account of the increased resort to Poor Law institutions in place of voluntary hospitals, they will not be such as to render the figures anything but startling. This being so, the Orthopaedic Section of the Royal Society of Medicine was well advised in choosing these injuries and their treatment for the subject of the discussion last week, and in asking so well qualified a member as Mr. Geoffrey Jefferson to open it. In his paper, of which an abstract will be found in our report of the discussion at page 1145, he dealt, as did most of the speakers who followed him, more with the symptoms and signs and pathology of these lesions than with the details of treatment. This is perhaps best accounted for by the reflection that the arrangement of the parts involved is somewhat complicated, and the mode of action of the forces concerned somewhat obscure, although essentially similar to the mechanism of fracture of a long bone from indirect violence. Nearly all indirect spinal fractures are the result of forced flexion. The few cases of fracture from hyperextension of the head are almost all confined to the odontoid process of the axis, and may be dismissed from present consideration. On the other hand, the opportunities of active treatment are few and small, and there is a very general agreement as to the principles of fixation and support on which treatment is based.

It is a commonplace of surgery that the gravity of every injury of the spinal column depends first on the presence of concomitant damage to the spinal cord which it contains or to the nerve roots which pass out through its foramina. It is perhaps less widely realized that without nerve injury a crush fracture of a vertebral body, unless early detected and promptly and properly treated, may cause long enduring or permanent weakness, by rendering the great main beam or kingpost of the body framework unequal to its normal functions apart from any lesion of the cord or its nerves. The effect of a compression fracture on the body of an individual vertebra is to change its outline, as seen in a

lateral radiograph, from what is roughly a parallelogram to a wedge like form. It is obvious that no surgical intervention can be expected to restore it to its normal shape at once, and that even partial spontaneous restoration, if it takes place, must be a very slow process. There is a general consensus of opinion in favour of treatment by long continued fixation, at first in the recumbent position, and the only serious difference of opinion is found in discussions as to how this fixation should be brought about. Some surgeons, mostly in America, are in favour of permanent fixation by means of Allbee bone grafts, others in Europe and America rely on plaster-of-Paris supports during the period of recumbency, to be followed by spinal supports of various kinds after the erect position and perambulation are allowed. There is no question but that this conservative method, which leaves the patient with a spine flexible in the affected region, gives, if successful, better functional results than any fusion method which permanently stiffens the back.

Dr. George Riddoeh, who opened the discussion on the neurological side, emphasized the importance in cases of cord lesions of delaying all operative intervention—if ever it be needed—until all symptoms of spinal shock had passed away, which might not be for two to six weeks after the injury. He confirmed the general belief, based on experience, that the pressure which damages the cord without destroying it is usually only exerted for a moment, and that any damage done is immediate and irreparable. Paralytic symptoms are very rarely due to irremediable compression, and hence operations for the relief of nerve symptoms are very seldom to be undertaken with any hope of success. In the diagnosis of the nature and extent of the injury the x rays are of the first importance, without them many compression fractures would escape detection, and even with them and it is in some cases very difficult to discover what is wrong. As Dr. Bertram Shries rightly insisted in the discussion, repeated exposures in different planes and stereoscopic pictures may be necessary before a decision can be come to. Such cases call for the highest skill and widest experience in the radiologist. Dr. Shries believes in the occurrence of subluxations of vertebrae which could be radiologically demonstrated and which, when undetected, might furnish opportunities for the triumph of irregular practitioners. Whether or not such cases are really slight subluxations or merely cases of adhesions is at present, we think, an open question. His reference to this problem of the non-detection of compression fractures opens another important question for discussion, which has recently been set forth by Dr. R. B. Osgood of Boston in an able paper read before the Section of Surgery of the American Medical Association last May.<sup>1</sup> After reviewing 242 cases of fracture of the spine he came to the conclusion that compression fractures are common injuries which are often not recognized early, and are consequently often treated by unsound methods, involving serious disability and medico-legal difficulties, and that if properly treated in uncomplicated cases a return to full wage earning capacity may be expected. He has a peculiar personal interest in this matter, for he tells us that he himself suffered and recovered from a crush fracture of the sacrum, sustained whilst skiing. In his experience, in the vast majority of cases only one vertebral body is crushed, and in some three-fourths of the cases this body is that of the eleventh or twelfth thoracic or the first or second

<sup>1</sup> *Journal of the American Medical Association*, November 5th, 1927, pp. 1553-9.

lumbum. It may be noted that in Dr. Osgood's series the incidence is much less in the cervical region than it is in the series of cases discussed by Mr. Jefferson or Mr. St. John Burton, in which the cervical cases were nearly as numerous as those at the thoracic lumbar junction.

Dr. Osgood strongly advocates conservative treatment such as we have outlined and would let the decision to insert a bone graft rest with the patient and not the surgeon. His paper is well worth careful study by all surgeons interested in this question and, in fact, no practitioner can be sure that he may not have to treat a spine damaged in a motor accident any day, and without warning.

## NORMAL TERMINATION OF PREGNANCY

The factors that cause the termination of normal pregnancy have always been a subject of speculation, but knowledge regarding this important problem has advanced very slowly. Recently, however, certain definite facts have been established.

The work of Dixon, Marshall, and Knaus in establishing the influence of the pituitary gland on the uterine activity during pregnancy was reviewed in these pages a year ago.<sup>1</sup> Dixon and Marshall showed that ovarian extracts increased the pituitary secretion but only when the extracts were made from ovaries which contained no corpora lutea, whilst Knaus showed that the effect on the uterus of administration of pituitary extract increased steadily towards the end of labour. The action of the drug on the uterus was measured by the ease with which abortion could be produced in rabbits.

The views expressed were not identical for Knaus was led to conclude that changes in the contractile power of the uterine muscle constituted the chief factor that terminated pregnancy, whilst Dixon and Marshall's work suggested that changes in pituitary secretion excited by the ovary were the chief cause. Knaus<sup>2</sup> has now furnished additional evidence for his view. The method he employed was to sterilize one uterine horn in each of a series of rabbits, to kill the animals at various periods of pregnancy, to remove the sterilized horns and to record their activity as isolated muscles. The presence of foetuses in the pregnant horns caused the muscle of the sterilized horns to undergo all the changes normal to pregnancy, but as their form was not altered by the development of foetuses in their interior their activity at different stages of pregnancy could be accurately compared. This ingenious method provided excellent records by means of which the changes of the activity of the uterine muscle could be determined very exactly. During the first half of pregnancy the uterine muscle showed a diminution in tonus and the contractions were much feebler than those of the non-pregnant uterus. During the second half of pregnancy the spontaneous activity of the uterus increased steadily both in amplitude and frequency and attained a maximum at parturition. These observations appear to indicate that parturition is the culminating event resulting from a gradual but steady increase in the excitability of the uterine muscle.

The reaction of the uterus to drugs also showed very interesting variations. Adrenaline and quinine caused powerful contractions at all stages of pregnancy, ergot and pituitary extract on the other hand had no effect during the first half of pregnancy but produced strong

contractions in the second half. The effects produced by pituitary extract in particular were much greater in the period immediately preceding parturition than earlier. If we accept Knaus's work we get a picture of an orderly change in uterine activity occurring throughout pregnancy, with parturition as the terminal event in the cycle. Parturition can thus be accounted for as a result of the changes actually occurring in the uterine muscle which changes, it is suggested, are induced by some hormone set free by the foetus. The possibility that the pituitary gland also plays a part is, however, not excluded since the sensitiveness of the uterus to pituitary extract is seen to change in such a remarkable manner as parturition approaches. This new work of Knaus therefore fits fairly well into the hypothesis outlined by Dixon and Marshall that one cause of the termination of pregnancy is a sudden increase in pituitary secretion excited by the ovary, in consequence of the regression of the corpora lutea.

## NOMENCLATURE OF DRUGS

A CORRESPONDENT has sent us the following complaint. He read in an American article a strong recommendation of a drug called methenamine as a urinary antiseptic. Inquiries made by the dispenser or his hospital failed, however, at first to identify any drug of this name, and it was only after some trouble that our correspondent learned from America that methenamine was the title adopted by the tenth edition of the *United States Pharmacopoeia* for hexamine. This is a very typical example of the confusion that is bound to arise if more than one official name exists in the same language for a single drug. We know that similar confusion is constantly arising in regard to many other common drugs which have different titles in this country and in the United States. In this particular instance the actual history of the nomenclature of the drug is as follows. The substance hexamethylene tetramine became known to the medical profession under the proprietary title of urotropine. It was included in the *British Pharmacopoeia* 1914 under the title hexamine and in the *United States Pharmacopoeia* IX, 1916 with the name hexamethylenamine. Although these titles were not identical yet they were sufficiently alike to prevent confusion but unfortunately in 1926 the name was changed to methenamine in the *United States Pharmacopoeia* X. We understand that this change was made because it was felt to be desirable to shorten the name and unfortunately proprietary rights were claimed in the United States of America over the name hexamine. Some similar reason will usually be found in most cases where a heterogeneous official nomenclature for a single drug puzzles and annoys the practitioners or medicine. Such histories obviously indicate a very unsatisfactory state of affairs. Medical literature is international and this is true in a special sense of all medical literature written in the same language. There is every advantage in having only one official name in the English language for any particular drug. One difficulty is that a large proportion of new drugs are introduced as proprietary articles, and it will usually be necessary for the medical profession to endure one change of name when such drugs are first introduced into the *Pharmacopoeia*. There is, however, no reason why more than one such change should be inflicted, and it is to be hoped that some international agreement will be obtained to ensure that when a name has once been introduced as an official pharmacopoeial name in either the United States or this country it shall be free from capture as a proprietary name and shall be adopted as the official name in both countries. The value to be

<sup>1</sup> BRITISH MEDICAL JOURNAL, 1920 II 602.  
<sup>2</sup> *Ibid.* *Proc. of Exp. Path. & Pharmacol.* 1, 152, 1927.

been introduced under proprietary titles is that an official and non-proprietary name often reduces the price of a drug by throwing its manufacture open to competition, but if the official names do not succeed in establishing themselves in common use they fail to serve this purpose. Now the task of obtaining a satisfactory official name for any drug that has been established under a proprietary title is always likely to be difficult, because the most suitable and obvious names are just the ones which are most likely to be subject to proprietary rights. Moreover, the proprietary name usually has a long start of the official name. If in addition to these unavoidable handicaps the official names differ in different countries, it must often happen that the official names will be ignored and the proprietary names retained in use.

### MECHANISM VERSUS VITALISM

RATHER more than a year ago Professor Eugenio Rignano's *Man not a Machine* was reviewed in our columns, and now, to show the other side of the shield, Dr. Joseph Needham, of the Biochemical Laboratory of the University of Cambridge, has contributed to the same series of little volumes one with the title, recalling the eighteenth century controversialists, *Man A Machine In Answer to a Romantic and Unscientific Treatise written by Sig. Eugenio Rignano and entitled "Man not a Machine"*. As if to prove that this plan of blast and counterblast has not originated with the publication of *Daedalus and Icarus* as a product of brighter biochemistry, Dr. Needham begins with an account of two somewhat similar books published 180 years ago—namely, "Man a Machine," written by Julien Offray de la Mettrie (1709-51), "a celebrated physician of the Faculty of Paris," and in the same year (1748) "Man More than a Machine," described as "in answer to a wicked and atheistical treatise written by M. de la Mettrie," by an anonymous person, de la Mettrie himself did not escape suspicion, for his methods bore a resemblance to his slightly senior contemporary Voltaire, he was, for example, guilty of a satirical lampoon purporting to describe the Medical Faculty of Peking, but actually ridiculing the leaders of the profession in Paris, he had to seek refuge in Berlin, where he became physician to Frederick the Great. Taking up the cudgels for de la Mettrie, whom the reader may at first be erroneously inclined to suspect he invented, Dr. Needham, with a light touch and very cleverly, contests the arguments of the vitalists, including one of the most recent, J. S. Haldane, and attacks Professor Rignano's argument that teleology, purposiveness, striving, aiming at a goal, is the unique characteristic of living matter. After a full and reasoned analysis of his opponent's thesis he draws together the threads of his essay in the concluding chapter, describing and discussing the methodological importance of mechanism in science and its inadequacy everywhere else.

### THE ROCKEFELLER FOUNDATION

THE report of the Rockefeller Foundation for 1926 opens with a general review of the work by the President, G. E. Vincent, which was published separately and noticed in our columns on August 13th (p. 289). This is followed by the report of the secretary, Norma S. Thompson, which shows that the programmes of the Foundation were carried out during 1926 by two boards and two divisions—the International Health Board and the China Medical Board, the Division of Medical Education, and that of Studies. The International Health Board promotes public health and

the prevention of disease by assisting Governments all over the world in the development of their own official health agencies. During the past year the Board took part in public health work of various kinds in eighty-eight States and countries throughout the world. It assisted Governments in yellow fever, hookworm, malaria, and general surveys, in campaigns for the control of yellow fever and hookworm disease, in demonstrations of malaria control, and in the development of public health organization in county and rural districts. Further, the Board has aided Governments in establishing or strengthening the technical services of public health work, such as sanitary engineering, the collection and interpretation of vital statistics, and public health laboratories. Numerous contributions were made to schools and institutes of hygiene for food, housing, equipment, maintenance, or endowment, for the London School of Hygiene and Tropical Medicine alone a pledge of 2,330,000 dollars has been made. Study tours for Government health officials have been continued, and fellowships in public health were provided for 253 men and women of thirty-one countries. The Board continued to co-operate with the Health Section of the League of Nations by contributing funds towards the support of international interchanges of public health personnel and in other ways. The total expenditure incurred by the Board since July 1st, 1913, to the end of 1926 amounts to about four million pounds. Much of the report is devoted to hookworm disease, malaria, and yellow fever, three widely distributed diseases of economic importance which the Board has chosen for special attention. The account given of these three scourges illustrates the great importance of primary field inquiries into the local circumstances of communicable diseases in order to ensure that subsequent administrative measures shall be as effective and economical as possible. Thus, in the case of hookworm disease it was found in Alabama that a temperature of 50° F. and under checks larval developments in the soil. In Mexico and in India it was proved that, besides temperature, the rainfall was also an important factor. Again, field inquiries in Tennessee showed that the hookworm larvae flourish only in sandy or loamy soil, and do not survive in clay or silt soil. Hookworm disease is chiefly found among those who work upon the soil, such as farmers and gardeners, but the Board's workers in China made the interesting discovery that, while hookworm disease is rare among the mulberry-tree coolies, it is relatively unimportant among the coolies on the rice plantations. In both industries human excrement is used for fertilization, but whereas large amounts of fresh excrement are applied to promote a rapid growth of the mulberry leaves, in rice culture the excrement used is stored for some time and in consequence most of the hookworm ova are destroyed. Moreover, rice cultivation is carried on under water, and this again prevents the development of the eggs. In general, the distribution of the disease was found to correspond closely with the economic circumstances of the population, where the people can afford shoes for the children and provide suitable latrines the parasite finds no foothold. The campaign against this disease has resulted in its almost complete disappearance from the United States and increasing control of its spread elsewhere. Every person harboring these worms does not suffer from them, for usually the amount of harm bears a direct relation to the number of worms, the Stoll dilution egg-count method, which demands a careful technique and is somewhat tedious, has been extremely useful in India in determining the intensity of the infection in various districts. Field investigations in malaria have thrown light on the species of mosquito conveying the parasite, and laboratory work has been devoted to the possible use of the precipitin reaction in the diagnosis of latent malaria and to suggested substitutes for quinine. An account is given

<sup>1</sup> *Man a Machine*. By Joseph Needham. Fellow of Caius College, Cambridge. *Psyche Miniatures General Series No. 12*. London. Hegan Paul Franch Trubner and Co. 1927. (Pott 8vo pp. 111. 2s. 6d. net.)

<sup>2</sup> *The Rockefeller Foundation. Annual Report for 1926*. New York. 61, Broadway. (Demy 8vo, pp. 450. 72 illustrations.)

of the West Africa Yellow Fever Commission, which started work in June, 1925, the disease is sporadic, but its endemicity among the natives has not been established. It appears from the report of the China Medical Board that in spite of civil wars and other disturbing events the work went on in 1926 without any serious interruption. This section of the report contains some particularly successful photographs and an imposing list of the papers published by the staff members of the Peking Union Medical College during the year under review. Dr R. M. Pearce, director of the Division of Medical Education, shows that representatives of the Division visited twenty countries in connection with medical education or co-operative programmes, and human biology and nursing education have been promoted by the Division of Studies. The reader cannot fail to be deeply impressed with the efficiency and widespread beneficence of this great Foundation.

### THE OPPORTUNITIES OF SPA PRACTICE

THE opportunities which spas present for collective research was the theme of the Samuel Hyde Memorial Lecture delivered by Dr Whitridge Davies to the Balneological Section of the Royal Society of Medicine on December 8th. He suggested that hitherto, notwithstanding the keenness and up-to-date outlook of many spa practitioners, such clinical research as had taken place at spas had been less fruitful than might have been hoped for from the amount of time and energy spent thereon. The reason possibly was that in much so-called research too great attention had been paid to the results of a single method of investigation or the alleged results of a single therapeutic procedure applied to a number of cases. The more promising method of clinical research was to study by every possible means the etiological factors involved, the symptoms and manifestations, the functional changes and the effects of various procedures in comparatively small groups of cases and this required co-ordinated effort. The lecturer went on to describe the physiological "background" for the investigation of disorders of joints and instanced some recent work on the nutrition of articular cartilage and the secretion of the normal synovial fluid matters on which textbooks of physiology were silent. He mentioned also the work of A. V. Hill and others on reflex regulation of tonus and pathological physiology of muscles related to diseased joints. From this he passed to the physiological basis of various balneological procedures, the effects of local heat upon the circulation, and of general heat and immersion upon circulation and metabolism, and again recent physical and chemical studies of various natural waters, radioactivity "zymosthenic" and catalytic activity, and the chemical "architecture" of salts and other constituents of such waters. Here were large fields of research offering complex problems which spa practitioners could appropriately tackle. A medical man in a spa, said Dr Davies was fortunate as compared with many of his colleagues in industrial practice who were often so overburdened with work that they had no time even to apply the knowledge they had gained as students not to speak of acquiring and applying fresh knowledge. He had, as a rule much more leisure, during a limited season he was extremely busy but for the rest of the year he had ample time to take mental stock, to improve his technical skill and to carry on research. In many health resorts the means for investigation and treatment were at hand while the number of doctors gathered there, with many different interests and points of view provided first-rate opportunities for combined research. The patients also owing to the chronic nature of their maladies or to their happier economic circumstances, were able to remain longer under observation. Spa hospitals had many empty beds during considerable periods of the year, and so were able to carry out

work which was not open to the voluntary hospitals in large towns where very few beds as a rule were available for any continuous investigation. But it was possible only by team work to take advantage of such opportunities as existed in spas. No one individual could hope to unravel more than a few threads of the tangle, but by working together much more could be done. The example of the Mackenzie Institute for Clinical Research might well be emulated by physicians in the principal health resorts. In one respect at least they would start with an advantage for while Mackenzie and his co-workers had to lay the foundations before they could build, many spas already possessed facilities for such work as had been done at St. Andrews.

### THE LOAD AND THE LAD

THE latest report (No. 44) issued by the Industrial Fatigue Research Board is entitled 'The physico-chemical changes in women in industry, a contribution towards the determination of the optimum load'. The painstaking investigations which are the subject of this report were due to a request from the Home Office. It is not clear, however, what evidence of serious damage to women in industry from carrying loads induced the Home Office to ask for an inquiry which has taken two years to complete, occupied the time of five experts, and led to the publication of a volume of 140 pages. Indeed it would appear from the report that no such injury occurs, or at most that it is limited to some boys who, when able to choose their own load occasionally attempt more than the expert deems suitable. Anthropometric data were first collected for 3,493 women engaged in industry, and as a control, for 413 unemployed women and 460 college women. This part of the inquiry indicated that the college women were taller, heavier and more powerful than the industrial women, that the strength-weight ratio was strikingly uniform for workers in good condition and that there was some evidence of a relation between "heaviness" of the trade and the physique of the women employed in it. The second section of the report deals with the physiological cost of the various modes of carriage to the individual worker. Departure from the erect posture, abnormality of gait, much static effort, strain (especially on the smaller joints), led to a higher physiological cost. The investigators in this section decided that 50 lb for 'well disposed' loads and 40 lb for 'ill disposed' loads were the maxima for women engaged in continuous work. It is interesting to compare this decision with a statement on an earlier page that girls in brick works carried three or four large bricks each weighing 26 lb supported on the left hip for a distance of seventy or eighty yards. The good carriage of the girls in this factory was also very remarkable. The third part of the report reproduces observations made by Dr Sybil Overton for the Chief Inspector and Senior Medical Inspector of Factories at the Home Office. This is perhaps the most illuminating part of the volume. She managed to discover two cases of alleged injury from weight lifting. A boy of 16 had a hydrocele which was said to have been caused by 'strain at the work' and a woman aged 22 believed that heavy work during the war led to a femoral hernia. Two surgeons on the other hand informed Dr Overton that in their experience so far as women and young persons were concerned heavy work alone was not responsible for injury and that some contributory factor was always present. As Dr Overton says this opinion was largely borne out when accidents said to be caused by weight lifting were carefully investigated. It was found that the highest percentage of load occurred in industries in which the worker could select his own load to suit his personal convenience, and not in industries in which he could not exercise his volition. Dr Overton is of the opinion that

the work required of the woman and the young person is, on the whole, well within their capacity, that the strongest women gravitate towards the heaviest industry, that women are generally self-protective in their choice of the size of load. But the justification for her errand is, in Dr Orison's opinion, the "young person." These individuals, especially the male young person (or, in homelier language, the lad), require "more regulation and supervision in their work if they are to avoid overstrain in the physically exacting period of adolescence." And the results of overstrain—when it occurs—are "the multiple sequelae of fatigue, increased incidence of accidents, lowered resistance to infection, increased suggestibility."

#### MYOPE CLASSES

THE National Committee for the Prevention of Blindness, which has carried on an energetic and effective propaganda in the United States for the cure of diseases such as trachoma and the prevention of ophthalmia neonatorum, has recently turned its attention to the establishment of "sight-saving classes," the American term for our myope classes. Last year the committee sent to this country two of its members to investigate our methods first-hand. The report is a generous recognition of the work done in this country for the education of the short-sighted. "England is the Mecca to which every supervisor and teacher of sight-saving classes in America turns with longing eyes, hoping that an opportunity may offer to visit the country in which this specialized education originated, and to note its development." A brief account of the general system of elementary and secondary education is followed by a history of the origin of the myope classes first formed in 1808 at the instigation of Mr. Bishop Harman as "a step for helping lame dogs over stiles." The character of the children eligible for the classes, the training of the teachers, their salaries, schedules, varieties in classes in different places, the manner in which the difficulties of rural cases are met, the curriculum of the town classes, health regulations, classroom accommodation, and the actual teaching methods are all reported upon. It is noted that the size of classrooms varies, not only in different parts of the country, but in the schools of any one place, and the London classrooms are criticized on the ground that many are too small, giving little room for the children to move about. "In fact, the conditions are sometimes so crowded that there is not space for the children to change the position of their seats so as to get the best light, or to pass to other parts of the room for different types of work without seriously inconveniencing other children." The report contains accounts of visits to the ophthalmic hospital school at Swansea maintained by the Metropolitan Asylums Board, to Birmingham and Bradford, to the private residential myope school conducted by Mrs. Bridge at Pitkdown, near Brighton, and to schools in Scotland. In summing up their impressions the delegates say: "In the myope school of Great Britain the visitor is impressed by the fact that the greatest emphasis is placed on the medical aspect. The medical inspection and follow-up work are most carefully and systematically done. The educational work for the most part appears somewhat subservient to the medical department. This is fitting and proper in many ways, as the main object for the existence of these classes as separate units is to save sight. On the other hand, this plan has some drawbacks. In most cases no attempt is made to keep abreast of the assignments of the regular schools. Some children are able to return to the regular schools, and are then at a disadvantage. Since competition is so keen in vocations, it is an added handicap to the pupils not to have the best education compatible with their eye difficulties." Then there follows this paragraph: "The myope schools are hampered by

conditions over which they have no control. The lack of sufficient funds is a most serious drawback. The teachers deplore the fact that there is practically no opportunity for special training. Improved lighting, smaller classes, and books printed in proper size type are all necessary improvements, but all would add materially to the cost of conducting the classes. In spite of the lack of these things, the myope classes are justifying their existence." An appendix contains a reprint of an article by Mr. Bishop Harman which appeared in our columns (February 2nd, 1924, p. 203) and a useful bibliography.

#### ETHICAL COURSES FOR MEDICAL STUDENTS

FOR many years the suggestion has been made it intervals that the medical student's education might usefully be rounded off with a lecture or lectures, given by an experienced general practitioner, on the proper conduct of practice. An experiment in this direction has now been made in London, and the November and December issues of the *St. Bartholomew's Hospital Journal* contain the text of a lecture on "Manners and customs in general practice," delivered at the hospital in October by Dr. L. G. Glover. The experiment was, no doubt, the outcome of an address which Dr. Glover gave to the Abernethian Society at St. Bartholomew's in 1925. It is interesting to compare the lecture with the syllabus, published last May in the *Journal of the American Medical Association*, of a course of six lectures which have been given during the past four years in the Washington University School of Medicine by the lecturer on professional conduct, Dr. Paul J. White. Dr. Glover, in a simple and straightforward manner, told the well worn path of English medical ethics, basing his discourse on the ancient rule in *Angustiman* monasteries for the master of the farmstead, that "he ought to be gentle, good tempered, kind, compassionate to the sick, and willing to gratify their needs with affectionate sympathy." If Dr. Glover had almost unnecessarily stress upon some of the rules of right conduct, this was as it should be in an address to beginners unacquainted with medical life. The American syllabus, on the other hand, though equally designed to keep the new practitioner in the narrow way of orthodoxy, is graminished with nesting subheadings. Thus, under the title "Acquiring practice properly" we find an item "Medical mismanagement." Advertising is dealt with as "legitimate" and "illegitimate," and practice may be improperly acquired by undue optimism or "alarmism." In the lecture on medical finance, after a description of the medical plight of the "genteel" middle classes, the student is instructed how to cope with patients "shopping" to learn size of fees for comparison with those of other doctors. For variety and topical interest, however, we are much impressed by lecture five, which embraces not only eugenics, euthanasia, and birth control, but also quackery and cults. A subheading of the last item concerns "pervasive practices of the medical profession itself, such as unwarranted glandular, elective, and intravenous therapy employed for effect"—the words "for effect" meaning here, no doubt, "to impress." We are not sure whether it is wise to introduce the student to all this, even sins of medicine at once. Perhaps he will find the middle path of Dr. Glover, which offers the amount of ideal, and here him, fortified with this tool of norms some of the more heinous wickednesses of himself.

THE President of the W.M.S. presided on December 13th at the distribution meeting of the General Council of King Edwards Hospital Fund for London. It was announced that the sum for distribution was £231,500, including a special grant of £34,500 from the Wells estate for extension and improvement. Further particulars will appear in our next issue.

## THE HEALTH ORGANIZATION OF THE LEAGUE OF NATIONS

### THE WORK OF THE CANCER COMMISSION 1923 TO 1927

When received from Dr. I. Pijl in the Medical Director the following summary of the work accomplished by the Health Organization of the League of Nations on some well determined cancer problems during the last four years. Before the Organization meets on the next phase of the 'march' it is thought that wider circles of the medical profession might well be interested in the results so far obtained.

This report relates to a corner of the field of cancer study which has been under the observation of the Health Organization of the League of Nations for the past four years.

The Health Committee in 1923 decided that from the international point of view there might be advantage in looking into the official figures of mortality from cancer as a whole, and particularly of cancer of certain sites of the body which have been furnished over a long series of years in certain European countries. England and Wales, Italy, and Holland were taken as specially suited for these comparisons, but auxiliary and complementary data from Switzerland and other nations in Europe and for some purposes from America also were laid under contribution. The investigation was made by a Commission of members of the Health Committee with the assistance of statistical, clinical and other experts, as well as of the Secretariat of the Health Section of the League. Its results promise to be of value both directly and indirectly. Directly they relate chiefly to cancer of two sites, the breast and uterus, which were chosen because fatal cancer of these organs is less likely than cancer of other sites to pass undetected or to be inaccurately reported as the cause of death. The Commission find that even when they have limited their consideration to these sites and deal solely with countries for which over a long period of years the national system of certification of cause of death has been well established and in many ways perfect of sources of error which seriously affect the proper comparison of the death rates between one country and another and even as between one part of the same country and another part. Much valuable knowledge can and should be obtained by the comparison of cancer death rates, but the Commission has found that in even one of the countries to inquire the certification of cause of death in relation to cancer is more or less unsatisfactory. There is particularly great uncertainty regarding the observance of the rule that cancer deaths should be referred in statistical statements to the primary site and not to the secondary site to which the final fatal result has ultimately been due. There is in the Commission's opinion urgent need of investigation in all countries possessing an organized service of statisticians of causes of death to determine exactly the degree to which certification by causes is unsatisfactory and how its scientific value may be improved.

The Commission with the aid of a distinguished anthropologist Dr. E. Pittard and an eminent statistician Dr. Nicotro made an effort to determine whether there was a relation in Europe between cancer mortality on the one side and race as judged by anthropometric characters on the other. The inquiry produced an invaluable monograph on the known facts regarding anthropological characters of different nations but the anthropometric data even more than the mortality data proved to be too defective and the Commission has sadly to record that its efforts show how much must yet be done before attempts to appraise racial elements in the prevalence of disease can be successfully undertaken. When a moment of consideration is given to the facile claims which have been made for individual nations and races that they are specially prone to be specially exempt from liability to cancer, this reasoned judgement though negative in character is not without practical value.

The direct results of the inquiry however have been by no means all of a negative kind. In each of the countries

concerned national expert work was undertaken to ascertain the circumstances in which so many deaths from cancer presumably preventable in large measure by early diagnosis and by early surgical (or radiological) intervention were occurring. Special observations were made of sample series of cases of cancer of the breast and uterus at particular hospitals and in selected areas as well as of the massed figures for the country as a whole. The results cannot fail to give a very considerable impulse and encouragement to the efforts which are being made in many quarters to organize a system of medical and hospital service and of popular instruction which will in fact prevent a large loss of life and the occurrence of a still larger amount of avoidable individual suffering. In a matter of this kind a wide survey, obtained by putting together or contrasting the experience of several countries differing in the type of their medical services in their hospital facilities and in the outlook of their people towards medical and surgical science is invaluable. The notable conclusion is reached by the Commission that when all these national differences are allowed for it is demonstrated everywhere that on the one hand early operation is a far more successful measure than even the general body of the profession suppose and on the other, that in fact the frequency of resort to operation remains deplorably low. This opinion in one form or another has often been expressed before but the value of the Commission's conclusion on the point is its authority derived from large and recent series of cases specially studied for the purpose and critically and judiciously analysed. It is well thus to be reminded that while we are waiting for more knowledge on the ultimate causation of cancer or on specific remedies to cure cancer we have already before us a glimpse of immediate practicable action which in respect of the sites of cancer at least is capable of reducing death and suffering from cancer to a far lower level than at present obtains. From this point of view of education the Commission's researches into the natural duration of untreated cancer and into various antecedent conditions connected with cancer at these sites furnish useful additions to medical knowledge. In regard to the influence of fertility they find from the experience of all the countries that a fertility below the normal for the particular nation is associated with increased liability to cancer of the breast while cancer of the uterus is to be associated not so much with fertility itself or with the number of pregnancies, but specially with the occurrence of a first pregnancy. The Commission lays stress on the evidence that cancer of the cervix is connected with conditions of labour particularly in primiparae which are in some measure preventable by the efficient management of the labour.

Indirectly the investigations of the Commission have been of value in each country in which they were pursued by helping to open up a comparatively new line of cancer research which may be called field work or team work. The questions at issue have required that in each country clinicians, surgeons, health administrators and statisticians should be brought together for consultation and to arrange for the suitable selection of case, the determination of other histories of operation cases and the assessment of results. This co-operation has in some cases been central and related to the country as a whole in other cases local in connection with a particular communal area or a particular hospital. But in every case it has been fruitful and the Commission urges that the organization of group studies of this kind should be extended to other countries and applied to all sites and varieties of cancer. On the completion of the studies now reported the Commission has undertaken the further duty of collecting and analysing for the consideration of the Health Committee of the League of different suggestions for applying the special opportunities of international scientific collaboration which the Health Organization at Geneva can furnish to the elucidation of other specified purposes of cancer research or for the prevention of cancer mortality. That the Health Organization of the League should compete with or overlap the mass of cancer investigation national and international already proceeding in every civilized country in the world would be an undeniable proposition but the inquiries summarized in the present report demonstrate that by the wise selection of appropriate matters for international inquiry the cancer studies made in individual countries or by individual investigators can be materially helped by this organization.

## UNDULANT FEVER

## AN APPEAL FOR THE DISCONTINUANCE OF GEOGRAPHICAL DESIGNATIONS

The unfortunate designation "Malta fever" has long caused annoyance to the inhabitants of the island. Although at the International Congress of Medicine in London in 1913 a resolution was adopted by the Section of Tropical Medicine and Hygiene substituting for it the descriptive term "undulant fever" (JOURNAL, 1913, II, p. 429), this improvement has been neglected, particularly by American and Continental authors, though it has been accepted by most British writers. The Malta Branch of the British Medical Association, in conjunction with the Camera Medica (Maltese Medical Association) has, therefore, issued the memorandum printed below appealing for the general use of the designation "undulant fever," instead of the term "*Micrococcus brucei*" instead of *M. melitensis*. The latter change is not discussed in this memorandum, in view of the proposal to hold an International Botanical Congress in 1930, when the general question of bacteriological nomenclature will be considered.

## Memorandum by the Malta Branch of the British Medical Association and the Camera Medica of Malta

1 A suitable and generally acceptable designation of this fever has long been the subject of discussion. The disease is one of those that have been labelled with a multitude of names. Thirteen appellations have been given to it on account of its supposed resemblance to typhoid or malaria, the character of its fever and the symptoms it presents give rise to fourteen other designations, and nine more were derived from the conditions which from time to time were considered to favour its prevalence. From the localities in which it was recognized and studied it came to be called Mediterranean fever, Malta fever, Italian fever, Neapolitan fever, Rock or Gibraltar fever, Cyprus fever, Crimean fever, etc.

2 The name "undulant fever," originally proposed by Captain M. L. Hughes, Army Medical Staff in 1897, was recommended by the International Congress of Medicine held in London in 1913, and is the one generally used by English writers. The terms "Malta" or "Mediterranean fever," however, are still frequently met with, and the purpose of this communication is to point out the objections to the use of these appellations, and to make an earnest appeal to all medical and scientific writers to discontinue them in favour of the more proper and less controversial one—undulant fever.

3 The term "undulant fever," though not perfect, is the most suitable designation of this disease in the present circumstances. As Hughes had pointed out, it describes one of the most constant and characteristic features of the disease—namely the undulations of the temperature curve. The temperature constitutes the primary, and although the only, clinical manifestation of the illness, and although the curve may not always be of the "undulant" type, yet the phenomenon is sufficiently frequent and typical to justify the adoption of the word "undulant" as a term which would clearly convey to any person the principal clinical feature of the disease. Parallel cases are the designation "typhoid fever," in general use for the disease in which the "typhoid" state is a frequent and silent but not constant symptom, and even more so the term "relapsing fever," derived solely from the variations of the temperature.

4 The term "undulant" has so far been used only for this disease. It cannot therefore give rise to ambiguity, and does not offer the same drawbacks as the terms "remittent" and "intermittent." Hughes had also rightly claimed that it has a familiar sound and is easily learned from the tongue, and is easily translatable into any language from the Latin form of *fibris undulans*. Its use has been accepted by many authorities whose attention has been called to the matter, and is continually gaining ground with scientific writers. It is continuing to have the test of time, and once that, accepting the objectionable geographical names, no other term has been more frequently used as a designation of this disease, the coming of a new name does not appear to be opportune at present.

5 It is urged that geographical names given to specific diseases are undesirable from a scientific point of view. They are mainly relics of the time when the miasmatic theory of disease held sway and each kind of fever was considered to be caused by "infective emanations" inherent to the particular country or locality where it prevailed. They have no relation to the symptomatology of a disease, or to any of its primary or secondary features, and are neither characteristic nor significant of its nature. As Sir William Aitken said when advocating the use of a general nomenclature of diseases: "Except in matters of history and as beacons to warn us from a greater danger to science, let these and such like names be consigned to oblivion." And, as a matter of fact, the disease which forms the subject of this communication appears to be one of the very few for which a geographical name is still in use.

6 A consideration of the history of fevers for the last 150 years brings home very clearly the part which the use of geographical names played in helping to retard progress in the unravelling of the nosology and etiology of diseases. This is specially evident in connexion with the "Mediterranean" group of fevers. Under such names were frequently grouped together indiscriminately such diverse diseases as typhus and typhoid, yellow fever, another fever accompanied by jaundice of doubtful nature, sandfly fever, relapsing fever, and probably malarial crises and other febrile diseases which are still unclassified.

7 The name "Malta fever" was eventually assigned to the long continued fever of the undulant type comparatively recently. Formerly by "Malta fever" or "Maltese fever" was understood the "simple undulant fever" of short duration now known as phlebotomus fever. Mastron, who was the first to give a detailed description of undulant fever in Malta (Army Medical Report, 1863), called the disease "Mediterranean or generic remittent fever," and clearly differentiated it from "simple undulant fever," which he continued to call "Maltese fever." Boileau (1866) described "Malta fever" as "a pyrexia with sudden onset terminated in seven days by lysis." Later on the term came to be applied also to fevers of longer duration (Maclean, Wood, Netter, 1876). It is evident, therefore, that the designation "Malta fever" cannot be retained for the fever of the undulant type on the plea of length or priority in use.

8 The fact that undulant fever is not confined to the island of Malta or to the Mediterranean needs hardly to be emphasized. It has been identified in other European regions and in widely separated localities in China and America, South Africa and India, etc. Nor, it may be mentioned, is it peculiar to the Maltese goats.

9 Recent observations that the *B. abortus* of Bang may give rise to a continued fever of the undulant type similar clinically to that caused by the *M. melitensis* of Bruce would furnish a further argument against the retention of the term "Malta fever." Whatever connexion there may be between the designations "Malta fever" and "*M. melitensis*," it does not hold good when the fever is due to the *B. abortus*. The adoption of the term "undulant fever" for the clinical condition, followed in each case by an indication of the causative agent—for example, undulant fever (Bruce), undulant fever (Bang)—should prove useful as in the case of the paratyphoids.

10 The prejudice to the moral and material interests of the island of Malta in consequence of the association of its name with a disease which is far from being peculiar or limited to the locality is considerable. The Maltese nation keenly resents the resulting stigma and feel that the reputation of their country has suffered mainly on account of the important research work on the disease that has been carried out in the island. The Government of Malta, in fact, has on several occasions considered it necessary to make representations on the subject.

11 The members of the 'Camera Medica' of Malta and of the Malta Branch of the British Medical Association have ventured to submit the above observations in the hope that their fellow members of the medical and allied professions will take them into sympathetic consideration, and that they will accept their suggestion for the general adoption of the designation "undulant fever," and for definitely discarding the inappropriate geographical names.

## HEALTH OF THE SCHOOL CHILD

SIR GEORGE NEWMAN'S REPORT

(Continued from page 1167)

ONE of the most notable expansions of the school medical service in England and Wales during the past year has been in the development of schemes for the treatment or crippling defects. New schemes were approved in forty-seven areas, bringing the total number of such schemes up to 132. Orthopaedic treatment in connexion therewith is carried out in 59 hospitals (and in 20 of these the education of the patient is provided for) in 122 school clinics and over 100 voluntary clinics. The ultimate success of any scheme in effecting the cure of crippling conditions must depend upon the early discovery and treatment of these conditions, the majority of which arise in pre-school life. Especially is this true of infantile paralysis, which is responsible for a large proportion of all cases of crippling. There is evidence of definite progress in the prevention of crippling defects. Tuberculous home diaries, one of the chief causes of crippling, shows a decline. Severe tickets, another important cause, have been diminishing for several years owing to knowledge as to its prevention. A complete local scheme can only succeed when there is (1) knowledge of the cripples or the area, (2) provision for remedial facilities, (3) following up of all cases and (4) measures for prevention. Provision must be made also for training and rehabilitation of the cripple and for a full range of suitable occupations so that each individual may be put to the most suitable employment.

*Treatment by Artificial Light*

Artificial light as a method of treatment for various defects and diseases has achieved great popularity during the past few years. It is a form of treatment which appeals vividly to the imagination, but experience shows that both skill and caution are required in its administration. The following notes are founded on the reports of school doctors. Dr Hill of Carshalton is of opinion that the treatment has no actual influence on the rate of gain of weight. Dr Saunders, tuberculosis officer of Croydon, notes that "the very debilitated anaemic, chronically delicate child appears to react adversely to the treatment. In cases of extreme debility the tissues do not appear to be able to respond, and the net result is a further drain upon the vitality of the child. This manifests itself in loss of weight, increasing listlessness and nervousness." In catarrhal conditions it was found that there was no diminution of the symptoms as a result of treatment. Rickets did not show any better response to light than it did to cod liver oil. In the treatment of surgical tuberculosis, on the other hand light has proved of great value. Children suffering from tuberculous glands do well; the effect is most manifest in those cases with discharging sinuses. The most successful results have been obtained in the treatment of lupus. Pronounced successes are reported in the treatment of psoriasis, impetigo and alopecia areata. There is very little evidence of any benefits obtained in the treatment of nervous conditions. Certain children become ill and irritable. Generally children become more cheerful but where strict investigation has been made as at Carshalton, it has not been found that artificial light has any lasting influence on either mentality or character.

*The Child before School Age*

Last year suggestions were made that the state of entrants should be the subject of special investigation. It is now clear that one-quarter to one-third of the children need medical attention immediately on admission to school. The defects found are constitutional. Not a mere defect just to be put right, but some degenerative process—in part hereditary, in part due to some lack of home nurture such as irregular feeding and lack of sleep in part due to infective fevers. In some areas there is an indication that conditions are better now than formerly, but London shows no change for ten years. A fault in methods is the fact that the child from birth to 5 years of age is under the maternity and child welfare authority, and thereafter the educational authority, and the two are separate

"There is no continuous supervision by the same authority." In a few cities, such as Liverpool there is continuity, for the authority is one and the same. There is evidence of a great need for more effective welfare service—something in the nature of an institution which combines the advantages of the day nursery with those of the nursery school. The nursery school seeks to remedy the defects often inherent in the conditions of home life as found in some parts, it aims at medical and social education and the provision of right environment, physical, mental, and social, for the proper development of very young children. Experience shows that tears lest the removal of such children from the home should result in lessened parental responsibility have little foundation, on the contrary, increased parental interest and co-operation for the welfare of the child is obtained. This is shown in improved cleanliness and nurture, both personal and domestic, a vider dietary, and in many cases more suitable clothing. Such schools should be closely associated with the school medical service, for the congregating of large numbers of young children or susceptible age demands the attention and supervision of medical officers, nurses and teachers skilled to detect early symptoms of disease and easy to take prompt preventive measures against infection. In many areas where mothers go out to work day nurseries are inevitable, but it is suggested that it would be better to have one type of nursery for all children under the school age in areas where the social condition makes such a provision necessary for the protection of child life. Such an institution might be established at or in connexion with the maternity and child welfare centre and near the local elementary school. Such a system would give the infant the advantages of habit training and medical supervision at the critical time and would relieve the school medical service of much of the disease which has to be faced when the entrants come under examination.

*Acute Rheumatism*

The hypothesis that acute rheumatism is the reaction of the human body to the presence of the *Streptococcus viridans* is mentioned with favour. It is noted that this organism is widely distributed, is frequently found as a harmless saprophyte, or as the causal agent in lesions which have nothing to do with rheumatic fever. If it be, as believed a common, perhaps constant habitant of the human body, attention must be concentrated on the conditions and predispositions which induce it to assume an activity which results in rheumatic fever. The organism cannot be annihilated, we must discover the means of fortifying the body against it. It is advised that the school doctor should search for any case in which there is suspicion of acute rheumatism, a register should be kept and these children watched, their work and attendance being modified. Facilities for consultation at a heart centre are recommended, with some hospital beds available and residential hospital schools for lengthy cases, and finally continuous after care. A detailed account of a scheme developed by an association for the prevention and relief of heart disease, organized in New York in 1915 is given. The completeness of the scheme depends on the close and willing co-operation between the officers of the school and public health services, the private practitioners and the staffs of voluntary hospitals, and the co-ordination of these by one man, of acknowledged skill and consultant standing, on the staff of the hospital and acting as expert adviser to the school medical officer.

*Health Teaching in School*

The teaching of hygiene is unequal and variable in form, the form itself is dependent upon the circumstances of the school. A competent and well informed teacher well supported by the local authority, will ensure an effective presentation of the subject. There are, however, many difficulties to be overcome. In some places the school premises and equipment do not provide a very favourable environment for health demonstration purposes, rather the reverse, in many schools the teacher has not yet devoted himself to a thorough understanding of hygiene and a wise exposition and interpretation of it, in many others the responsible authorities have let hygiene be crowded out of

the curriculum, failing to understand its value. It is suggested that for children under 11 years of age there should be a periodical and, if practicable, a daily lesson in health of a few minutes' duration. It should be directed to healthy habits, with illustration of, and the requirement of, clean hands, clean hair, clean teeth, and the requirement becomes a habit. The child should become accustomed to fresh air in the classroom, be taught to breathe with mouth shut, trained to sit squarely, and to use sanitary conveniences decently. For older children the lessons might be associated with the teaching of elementary science (chemistry, physics, and biology). It should be less a school subject than an integral part of the whole life of the school. The Board of Education is publishing forthwith a special handbook of suggestions to teachers on the teaching of hygiene.

#### Investigation and Research

That the school medical officers are keenly interested in the increase of medical knowledge is shown by the list of individual investigations undertaken by them. Besides, there have been collective investigations on certain subjects. There are committees at the head office for co-ordinating these particular investigations. One on enlarged tonsils and adenoids, another inquiring into defective vision, an anthropometric committee, a committee on mental deficiency, and on the physical condition of "entrants."

In his conclusion Sir George Newman remarks that this year's report makes the nineteenth issued since 1908. The series constitutes a sort of Doomsday Book of the physical condition of the English child for that period. It is only by the careful study of the actual facts over a period of time that we can appreciate the influences and conditions which affect not only the child's school days, but the whole life of the individual. Education, occupation, production, heredity, even character, are dependent upon physique. That is, and must remain, the bedrock. If it fail us all else will be imperilled. We may design admirable schemes of education in literature, science, and the arts and crafts, and reform and adjust them from time to time, but if the pupil does not possess a healthy and well balanced body, unimpaired special senses, a "thinking hand," and an alert and developing brain, we labour in vain, and our schemes may come to naught.

*Correction*—There was a printer's error in the notice of Sir George Newman's annual report to the Board of Education published in last week's issue of the JOURNAL at p. 1106. In the small print under the heading "Nutrition" (column 2) he is quoted as saying "Insufficient sleep, chronic fatigue, absence of fresh air, and lack of exercise are exerting a very good influence," etc. The word "good" so obviously incorrect, should have been "great."

## Scotland.

### DR C E DOUGLAS

A LARGE company from the town of Cupar and county of Fife assembled in the County Hall, Cupar, on December 8th when a testimonial was presented to Dr C E Douglas on the occasion of his retirement after fifty years of active medical practice in the town of Cupar. Provost H J Smith presided, and the presentation was made to Dr Douglas by Sir Ralph Anstruther, Lord Lieutenant of the county. He said that Dr Douglas was not only greatly esteemed as a medical man, but he had played a large part in the social life of the community. He had been a great worker in the Volunteer Force and afterwards in the Territorial Army, while during the war he had set a fine example in the public service by his work in the Royal Army Medical Corps abroad. Dr Douglas, in reply, said that he had all his life suffered from a disability of looking younger than he really was. He considered that during his fifty years of medical experience the greatest advance had been the rise of preventive medicine. He believed that the present practice of taking children once or twice a year to be examined by a doctor was not sufficient, and every man and woman over the age of fifty should be periodically examined in a similar manner, no matter what was their state of health. In this way many ailments could be checked at an early stage. It may be recalled

that Dr Douglas graduated at Edinburgh in 1877 and afterwards took the M.D. degree of that university, the F.R.C.S. Ed. in 1898, and the D.P.H. of Cambridge in 1894. He served as a temporary surgeon with the South African Field Force, when he was made an honorary captain in the R.A.M.C. and during the great war he acted as a lieutenant colonel in the R.A.M.C. with the Expeditionary Force. He has been a prominent member of the British Medical Association, in which he has held many offices, including those of chairman of the Scottish Committee and a member of Council of the Association. He received the honorary degree of LL.D. from his university last July, during the Annual Meeting at Edinburgh. In his retirement Dr Douglas has taken up residence in St. Andrews.

### FUTURE OF SCOTTISH HOSPITALS

The Government's hospital policy and the future relations of the public authorities to voluntary hospitals were discussed on December 9th at a meeting between Sir John Gilmour, Secretary of State for Scotland, and a deputation from the Scottish voluntary hospitals. The meeting took place in the offices of the Scottish Board of Health at Edinburgh, and the deputation was introduced by Colonel J A Roxburgh, chairman of the Scottish Regional Committee of the British Hospitals Association and chairman of the Glasgow Western Infirmary. The deputation was representative of voluntary hospitals in Edinburgh, Glasgow, Aberdeen, Dundee, Falkirk, Stirling, Paisley, Dumfries, Inverness, Greenock, Dunfermline, and Perth. Colonel Roxburgh explained the object of the deputation, which was a desire to put six questions to the Government in regard to co-operation between public authorities and the voluntary hospitals. The hospital position in England and that in Scotland were different. In Scotland there was an estimated shortage of some 3,600 beds, and the voluntary hospitals were in favour of co-operation with the public authorities, but felt it necessary, specially in view of the proposals for Poor Law reform, to obtain a lead from the Government on the methods of co-operation likely to be adopted. The questions were as follows:

- 1 Is it proposed to establish a unified hospital service in Scotland?
- 2 If the answer is in the affirmative, would the statutory hospital service cover the whole field of medicine and would it work in competition with the voluntary hospitals?
- 3 Who is to provide the necessary additional beds after the present building programmes of the voluntary hospitals are completed?
- 4 Will the voluntary hospitals and the public authorities work in co-operation round the voluntary hospitals as centres?
- 5 Is it proposed to give financial aid to the voluntary hospitals as recommended by the Mackenzie Committee?
- 6 Is there any need to establish a statutory general hospital service?

Sir John Gilmour, in reply, said that he was glad to have the opportunity to discuss a question of such vast importance to the country. He thought that the problem might be varied in different parts of the country, and it was perhaps not possible to lay down a common policy. With regard to the future of the Poor Law system, he thought it was safe to say that in any scheme it would be necessary to have larger units. He assured the voluntary hospitals that they had no reason to apprehend that anything inimical to them would result from Government action. He and the Minister of Health agreed that the Government's object must be to conserve the voluntary system, for the voluntary hospitals had maintained and improved their position, and Scotland especially had reason to be proud of the position of those hospitals. Taxpayers and ratepayers had enough difficulties at present without facing the burden of cost of the whole hospital services. He could not, however, commit the Government on the subject of a proposed grant, but he looked to co-operation between the public authorities and voluntary hospitals for the future development of hospital services. He agreed with the view that the co-operative arrangements should centre round the voluntary hospitals. Some advance on co-operative lines had already been made—for example, at Stirling, Falkirk, Aberdeen, and Glasgow. As part of the solution of the increasing demand for hospital services he thought that the Poor Law hospitals must be brought up to the standard of the voluntary hospitals. He suggested

that the voluntary hospitals might appoint a small committee of three or five persons to act as a link between the Regional Committee and the Department.

A general discussion thereafter took place in which several of the speakers endorsed the proposal to extend the system of paying patients in the general hospitals. It was also suggested that a Government grant for capital expenditure would probably solve the difficulty so far as Glasgow was concerned. At the close of the meeting a liaison committee, as suggested by the Secretary of State, was appointed as follows: Colonel D. J. Macintosh and Dr. MacLachlan from Glasgow; Sir David Wallace from Edinburgh; Mr. C. I. Henderson from Dundee; Mr. Thomson from Stirling; while a member still remained to be nominated from Aberdeen.

#### PRESENTATION TO DR. MURRAY INVERNESS

A complimentary dinner of physicians in the counties of Inverness, Ross, and the neighbouring areas was held on December 3rd to celebrate the jubilee in medical practice of Dr. James Murray. Dr. John W. Macenzie, Inverness, presided, and the health of the guest of the evening was proposed by Dr. John Macdonald, M.O.H. for Inverness town and county. He said that the credit of introducing antiseptic principles in surgical treatment in the North of Scotland belonged to Dr. Murray who had been a pupil of Lister at Edinburgh University where he had graduated in 1870. In returning thanks Dr. Murray said that his period as a student had been a very interesting time when the discoveries of Pasteur and Lister were revolutionizing the practice of medicine and surgery. He had been a prisoner in the class of Lord Lister, and had later acted as house-surgeon in Edinburgh Royal Infirmary under Sir Patrick Heron Watson. The students of that time had been impressed with the wonderful success of surgical cases obtained in Lister's wards as compared with the greater tendency to sepsis in other wards of the institution. He mentioned that the poet Henry had been a patient in Lister's ward at the time in Edinburgh Infirmary.

## Ireland.

#### RETIREMENT OF PROFESSOR PEARSON OF CORK

HAVING reached the statutory age Professor C. J. Pearson has retired from the chair of surgery at University College, Cork. On November 19th Professor Pearson gave a valedictory address to his students in the examination hall of the college. Many of his old pupils from the city and county were also present together with his colleagues on the teaching staff of the college. He reviewed his long connexion with the college as a teacher, starting a demonstrator or anatomy, then for many years as professor of materia medica and lecturer in medical jurisprudence and finally since 1900, as professor of surgery. Originally a graduate of Queen's University of Ireland he saw that institution replaced by the Royal University and the latter by the National University of Ireland. As a mark of their appreciation of Professor Pearson's services to the teaching of medical science his colleagues are anxious to perpetuate his name in the college by founding a 'Pearson' prize or medal to be awarded at the final M.B. examination. A committee has been formed and invites the co-operation of Professor Pearson's old pupils at home and abroad. Subscriptions limited to one guinea, may be sent to Dr. W. J. O'Donovan, Pathology Department University College, Cork.

#### SAMARITAN HOSPITAL BELFAST

The extension of the Samaritan Hospital Belfast is now making good progress, and on December 5th Viscountess Craigavon accompanied by her husband the Prime Minister of Northern Ireland laid a commemorative stone. The new building will double the accommodation of the institution. Two large new wards will be available on the ground floor and the additional accommodation will enable the hospital to extend its sphere of usefulness. Sir Thomas Dixon who presided in proposing a vote of thanks to Lady

Craigavon, recalled that the hospital was founded in 1872 by Sir M. Mordecai College Street. After a year or two the premises were found too small but, thanks to the generosity of Mr. Edward Benn the hospital was able to remove to its present site. In 1897 the accommodation was found unequal to the growing requirements, and the late Mr. Forster Green added a wing at his own expense. Later it again became evident that the hospital premises were not large enough, and Lady Craigavon issued an appeal and organized a very successful bazaar, with the result that the committee was in a position to build the present extension. Lady Craigavon is replying to that a magnificent response to the appeal had been made in the six counties, and she was sure that the contributors would feel that they had in the Samaritan Hospital an institution worthy of the city of Belfast. Though the response had been generous it was still necessary for the maintenance of the hospital that the subscription list should continue to grow, and she urged that the public in going through their charity lists at the beginning of the year, should bear in mind the needs of this excellent institution.

#### VACCINATION IN WEXFORD

In the Dail recently Mr. Michael Jordan asked the Minister for Local Government and Public Health whether he had issued to the County Wexford Board of Health a threat of mandamus because of their failure to enforce the vaccination laws, whether he was aware that the vaccination laws had been in abeyance in that county for the last twenty years, and that in an attempt to enforce them now would involve the ratepayers in very heavy expense for legal proceedings, and whether he was prepared to introduce legislation for the purpose of amending the vaccination laws to exempt conscientious objectors. General R. Mulcahy, Minister for Local Government and Public Health, in the subsequent debate said that he could not hold out any hope to the County Board of Health in Wexford that he would not do everything possible to enforce the vaccination laws there and in every other county in the Saorstát. He did not know what Deputy Cornish meant by saying that attention was paid to sanitation; they need have no fear of smallpox. He did not agree that the vaccination laws had been in abeyance in Wexford for twenty years, though there had been a certain amount of agitation against vaccination there for some time past. The medical officer received 2s. for every vaccination case and whenever a notice had to be served on a person who had not arranged for his child to be vaccinated during the statutory period it cost 1s. legal expenses were however another matter. In January, 1925 the urban district council had taken over the administration of vaccination from the board of guardians or New Ross, which had a population of 5,609, the average yearly number of birth being 112. Since 1925 the Board of Public Health had endeavoured to administer the vaccination laws there and 763 successful primary vaccinations had been performed. There had been some legal expenses in the case of 33 defaulters prosecuted recently. The total legal expenses in connexion with vaccination since January 1925 including the 33 defaulters in New Ross were £21 14s. 7d. so that the cost of having the vaccination laws put into force properly in Wexford was not going to be excessive. It was clearly shown that there was a present danger because of the position with regard to smallpox there was no reason to believe that the Wexford people would not be as efficient as any other people in the country. While the point had been raised that adults were unprotected by their first vaccination and were liable to contract smallpox it was known that childhood was a dangerous period. It was worth noting in connexion with the present outbreak in England and Wales that in 1926 there were 10,141 cases of smallpox. An analysis of the figures showed that complete immunity against the disease was conferred by vaccination under the age of 12 years and that no more of young children who had been vaccinated were attacked by smallpox. Indeed, such was the efficacy of infant vaccination that only eight children who had been successfully vaccinated contracted the disease under the age of 15 years whereas amongst the unvaccinated children of the same age period

the disease developed in 4,840, with fatal results in seven cases. If they were not prepared to follow Prince and Germany in having adult vaccination at a particular period, they could be assured that infantile vaccination would protect the children of the country up to the age of 12 almost completely against the danger of small-pox. The cost of a small-pox epidemic was very heavy, for in addition to the charges for vaccination, there were expenses for medical fees, special nurses, and destruction of clothing of cases and contacts. The person attacked was laid up for three to twelve weeks, and the contact case was isolated for twelve to twenty-three days. It would be rash to assume that there would be no outbreak simply because they had had only eleven cases. Within the last two years a serious situation had arisen in England, and owing to the way in which small-pox was carried they might very possibly find a number of cases springing up in their midst in persons who had come from England, the disease only developing in Ireland. If it was thought that there was no sound medical basis to their present vaccination laws the position ought to be stated from the medical point of view.

In an interview given to the press a few days later Dr E F Stephenson, chief medical officer of the department, declared that Wexford was a danger to the community. For twenty years the vaccination laws had been in abeyance in the county, and the inspectors had protested against the present attempt to enforce them, on the ground of expense. If a person infected with small-pox came there, he added, the disease would spread widely, and the expense could be imagined when it was considered that the isolation and treatment of a single case at Cobh, Co Cork, cost £183. Living, as they were, with their ports in constant communication with Great Britain, they must certainly regard seriously the presence of the extensive and dangerous outbreak of small-pox in that county, and they would be neglecting very serious duties if they did not point out the danger, or left anything undone to secure that the vaccination laws were administered to the greatest possible extent.

## England and Wales.

### MEDICINE AND LAW AT DINNER

THE annual dinner of the Medico-Legal Society was held at the Holborn Restaurant on December 9th under the presidency of Sir William Wilcock, when the principal guest was Mr Justice McCardie. The usual toast of "Medicine and Law" was proposed in a few sentences by Sir Russell and responded to by Lieut-Colonel C T Sumner (Warden of the Society of Apothecaries), and by Sir Leonard Keirshaw (Registrar of the Court of Criminal Appeal). Mr Justice McCardie, in proposing the toast of "The Medico-Legal Society," reminded the gathering that the society was founded twenty-six years ago. How the wise physicians and lawyers of past times would have rejoiced over such a union of their professions! It would be deplorable should anything arise to cause antagonism between medicine and law. The two professions had much in common especially in the fact that they both jealously preserved their traditions. Mr Justice McCardie vowed himself a great lover of the law, conceiving it as an edifice beneath which all citizens might take shelter, and he looked upon medicine also with deep respect, recalling the remark of an old writer, "When I read the history of disorders I wonder that men can live but when I read the history of cures I wonder that men can die." There were two things which might lead to antagonism between the professions. One of these was the question of insanity and crime. He did not believe that the law was unprogressive, or that the social and scientific philosophy of 1927 must necessarily be the same as that of 1845 but he thought this question ought to be placed on a wider basis than that on which it was commonly taken. In newspaper and other discussions on the subject insanity in its bearings upon crime was always treated from the aspect of murder

whereas, in fact, it ought to be considered in relation to very many lesser crimes. The other question was medical secrecy—a vital question to the medical profession, as he himself had reason to know. But again he pleaded for a broader view. The medical man was naturally eager to break down the legal obstacles in the interests of public or individual health, and he respected his point of view, but the lawyer also had his ideal, which was the elucidation of truth, the very root of criminal justice. "Justice," said Daniel Webster, "is the great interest of man." He knew of no other test to apply to both these questions than the test of utility, the Benthamite test—the greatest good of the greatest number—and if that test were applied it would be found that the problems were by no means capable of the simple solution which was taken for granted in some quarters. Sir William Wilcock paid a tribute to his predecessor, Lord Justice Atkin, who had been president of the society for seven years. The great advantage of the society was that every new development bearing on medico-legal science was discussed from the double aspect. The past few years had seen not only an increase in membership, but a fresh stimulus to discussions. He hoped to see medico-legal work much better co-ordinated, it possible by the establishment of some institute in London, where teaching and research in forensic medicine could be advanced. Dr F G Crookshank, in a witty speech, proposed the health of "The Guests," and Sir John Anderson, Permanent Under-Secretary to the Home Office, and Mr Herbert Carson, president of the Medical Society of London, made brief responses.

### BRISTOL MEDICAL SCHOOL DINNER

THE annual dinner of the Bristol Medical School was held on December 8th at the Berkeley Cafe, Bristol, under the presidency of Professor J A Nixon, CMG, the guest of the evening being Colonel T Smeaton, CB, MP, emeritus professor of surgery in the University of Belfast. The President, proposing the toast of "The Guest of the Evening," said that Professor Smeaton was the first member of Parliament to be welcomed by them as an honoured visitor. He was usually returned unopposed for Belfast University, and had once had the singular distinction of being, for a few hours, the first and only member of the House. In 1914 he was selected as principal medical officer of the army of Ulster, but, as events turned out, he was not required to function in that capacity, and became instead one of the consulting surgeons to the British Army. Professor Smeaton proposed the toast of "The Bristol Medical School," and complimented the citizens of Bristol on their liberal financial support of their University. He recalled many well known names of past members of the medical school, and paid special tribute to Colonel Paul Bush, CMG, and Professor Hey Groves. Colonel Bush and Mr R H Moore responded for the school, and Mr S V Stock proposed "The Health of the President."

### PROFESSOR R HOWDEN

Professor Robert Howden retired on September 30th last from the chair of anatomy and post of registrar at the University of Durham College of Medicine, Newcastle-on-Tyne, and a testimonial fund is now on foot to recognize in some fitting way his invaluable work as an anatomist, teacher, and administrator. It is felt that his old students will welcome an opportunity of expressing their gratitude for what he has done for them, while colleagues and other friends in Newcastle and elsewhere will join in appreciation of his work for anatomy, and in particular of his devoted services to the medical school for the long period of thirty-eight years. It is suggested that the testimonial should take the form of a small memento and a cheque. The present students are desirous that the presentation should also include a memento from them. A strong general committee has been formed, and contributions already amounting to some £400 have been received by the executive committee, of which Dr S Whitley Davidson is honorary secretary. Further donations should be sent to the honorary treasurer, Sir Joseph Reed, at the College of Medicine, Newcastle-on-Tyne, before the end of the year.

## MEDICAL TREATMENT OF LONDON SCHOOL CHILDREN

It was reported to the London County Council on November 23rd that the popularity of treatment for school children continued to increase and that during the last six months the centres had been exceptionally busy. The total number of children treated during the half year to September 30th was 129,128, as compared with 114,223 during the corresponding period of last year. Increased provision has been necessary for the treatment of eye defects and conditions of the ear, nose, and throat. Ring worm cases have fallen off, and the provision under this head is decreased. The process of treating ear cases by ionization has been continued at five special centres, the number of ear cases ionized last year was 1,392. New treatment centres to be opened in 1928-29 include two for in-patient treatment of throat cases, one centre for eye defects, two for minor ailments and two for dental treatment. The total number of cases for which provision is authorized is 265,000, as compared with 254,000 last year, and the cost of the arrangements will be £102,500, an increase of over £4,000 on the year. At the same meeting of the council the education committee reported on the special clinic at Guy's Hospital, set up as an experiment for one year, for the treatment of children found to be diphtheria carriers. The number of children treated during fourteen months was 102. The committee was informed that considerable benefit had been derived from the treatment and it proposed to make arrangements during 1928-29 with selected hospitals for the treatment at special clinics of child carriers. The expenditure involved is estimated at £200.

## Correspondence.

## TREATMENT OF CANCER BY RADIUM

SIR—Dr Fletcher Shaw (December 3rd, p 1054) evidently belongs to the school of diehards who assert that the Wertheim operation is the one and only treatment for cancer of the cervix. He repeats the challenge which Victor Bonney has so frequently thrown down that when statistics are published in this country showing that cases of carcinoma of the cervix treated by radium have as high a percentage of non-recurrence after five or ten years as have those treated by Wertheim's hysterectomy, I will most gladly abandon this operation which until then I feel compelled to advise and perform. Apart from the fact that this is a direct repudiation of other clinics' results, notably that at Stockholm, which I have had the privilege of visiting and an experience which confirmed me in the unreserved acceptance of their reports, this attitude can only be that of one insufficiently experienced in the method condemned. He asks for the production of statistics which are comparable to any produced by the advocates of operation, for instance, Bonney, claims to have an operability rate of 63 per cent which means that he considers there is a chance of excising the malignant disease in that number of cases. In the treatment of approximately 300 cases by radium I cannot estimate the operability rate, but my treatment rate is 96 per cent.

The relief obtained from radium is acknowledged by the most sceptical and is only denied to those with fistulae, malignant exheria and the presence of severe septic infection of the pelvic organs. These constitute 4 per cent of patients presenting themselves for treatment. The question arises whether the more advanced cases are to be refused treatment in order to obtain statistics which would satisfy Bonney and Fletcher Shaw. Radium enthusiasts might easily turn the tables by telling their critics that until their operability rate is 96 per cent they have no statistics in common. The Wertheim school declines consideration of the unfortunate people, save into the two divisions of operable and inoperable and the latter are left as an unconsidered trifle, whereas most of them are eligible for radium. I have reported a number of cases treated by radium, only to have them compared with operative results, which, of course was a comparison of the unlike. From my experience I have no doubt that radium does permanently cure cases of cancer of the cervix, and, could

we but decide upon the virulence of a tumour by clinical or microscopical examination, it would materially help in the decision to be taken. Finally I have to declare that I am not prejudiced on this question, for I treat some of these cases by Wertheim's operation, some by radium and operation, and some by radium and x-rays—I am, etc.,  
London W 1 Dec 3rd. SIDNEY FORBES, F.R.C.S.

SIR—Dr Fletcher Shaw's letter in your issue of December 3rd (p 1054) conveys a definite challenge which, as the present radiologist to the Manchester and District Radium Institute, I feel compelled to take up.

I agree with Dr Fletcher Shaw that no definite statistics have been published in this country on a five- or ten-year basis, but statistics on a five-year basis have been given by the Radiumhemmet, Stockholm, and I see no reason why a particularly insular attitude should be adopted towards these. I quote those given by Donaldson in your issue of May 9th, 1925 (p 679).

Of 181 inoperable cases treated 166 per cent were well after five years.

Of 36 operable and borderline cases 40.5 per cent were well at the end of five years.

However, the main point is this. Dr Fletcher Shaw has used the words, "Unfortunately I have to form my judgement upon the results obtained in my own cases." He advocates the statistical method of argument in favour of this or that treatment for carcinoma of the cervix uteri, and in coming to the conclusion that operation is, in his opinion, preferable to radium treatment he bases it upon the results of his own cases. As an argument this would be more conclusive if his exact figures were given (a) in his cases treated by operation, (b) in his cases treated by radium—I am, etc.,

Manchester Dec 10th G E BIRKETT

## LATE RECURRENCES OF BREAST CANCER

SIR—In your leading article (p 1100) on the Medical Society of London's report you appear to doubt the direct effect of radium on malignant cells and attribute any beneficial effects to stimulation of the surrounding connective tissue. But surely Dr Canti's experiments on the effect of x-rays and radium on growing tissue cells would disprove this theory, and how can the extraordinary effect of radiation on a very sensitive growth such as lymphosarcoma—sometimes visible within five or six hours—be explained but by a direct effect on the malignant cell? Many clinical and experimental observations indeed show there does exist a direct effect as well as an indirect one by way of the connective tissue, vascular, metabolic, or other changes.

Again, you say that "controlled observations do not tend to confirm the utility" of post-operative radiation. Here it is essential to take into account variations in radiological technique. There are errors of deficiency and of excess, the first shown, I believe at the Cancer Hospital, where we must conclude the technique some years ago at least was as recommended by Dr Robert Knox in his book—the first dose along the line of the car unfiltered" (Radio-therapeutic, 1918, p 462). A result of this might be a stimulation of any remaining cancer cells below the skin level. But the existence of a stimulation dose is challenged by the Vienna school and is not yet definitely proved or disproved, either experimentally or clinically. And any stimulation might be a result of the operation, as I have seen seven or eight cases with rapid widespread local recurrences coming on within a few months of operation in which no radiation had been given.

On the other hand excessive treatment as by the so-called Erlangen method used for post-operative cases has led to an increased proportion of recurrences in some clinics, it is used for primary, but not for prophylactic work at Erlangen itself. Certain glancing intensive methods may be employed, but the best prophylactic results so far have been with a medium technique.

I hope to publish soon details of a number of successful primary, recurrent, and post-operative cases from the Middlesex Hospital, from a series of over 500 treated by x-rays and radium—I am, etc.,

London W 1 Dec 10th J H DOUGLAS WEBSTER

## TRAUMA AND MALIGNANCY

SIR,—In a recent communication to the *BRITISH MEDICAL JOURNAL* Sir G. Lenthal Cheetham asks whether anyone has met with the development of a tumour in a wound inflicted on a combatant during the late war. The following case may be of use and interest, it certainly was sad and dramatic.

A man aged 35, of the New Zealand Expeditionary Force, was wounded by shrapnel in the right jaw and submaxillary region in 1918. He stated that the shrapnel was never removed, and that the wound healed well and gave him no trouble until 1920, when he experienced occasional swelling and tenderness.

In April, 1923, when in the country, he had what he thought was an attack of toothache, and a swelling appeared below the jaw in the situation of the old wound. The swelling got rapidly larger and he went to a town, where the supposed abscess was opened. He was sent to me on May 9th, 1923. As the swelling was in the region of an old wound I thought it might be due to some foreign body. A ray examination did not show any shadow, but revealed an abscess cavity at the apex of a lower molar—the only tooth on that side. The tooth was loose and tender. I explored the swelling as he had a temperature of  $100^{\circ}$  and a pulse of 100, and the former incision was suppurating. I immediately found that it was an extensive neoplasm necrotic in the centre. He was given massive doses of x-rays (the radiologist did not recommend radium), but the tumour grew with most alarming rapidity, the increase in size could readily be appreciated from day to day. In eight weeks he was dead, with a huge fungating mass on the right side of the neck.

Professor Drennan and myself were unable to agree as to the precise pathology of the tumour, so we submitted history, photograph, and sections to Professor James Ewing of Cornell University, and the following is his reply:

'In the remarkable case of tumour of the jaw, of which you send me history, photos and sections, I have been unable to reach a positive conclusion regarding its nature. From all the facts I am inclined to think that you had to deal with a very malignant osteogenic sarcoma, and one which took the form of spindle cell growth without new bone formation. These tumours arise from the periosteum. The structure in the sections is much altered by inflammation.

"I would rule out adamantinoma on the rapid growth, fungation, ulceration, and structure. There are always distinctly epithelial structures easily recognized in adamantinoma, and I find no such structures in this section. I could also find no signs of epidermoid carcinoma.

The question had previously arisen for pension purposes, and liability was admitted by the pensions department. This is the only neoplasm following war injury I have seen. I am occasionally, however, asked whether of the numerous skin grafts made in mucous cavities some will not become malignant—the whiteness of the graft probably prompting the idea. I can only say I do not think so, and have not seen anything indicating such a possibility.—I am, etc.,

Sydney N.S.W.

H. P. PICKERILL, C.B.E., M.S.

## TREATMENT OF PROSTATIC ENLARGEMENT

SIR,—I was much interested to read Sir Cuthbert Wallace's Bradshaw Lecture on prostatic enlargement (November 19th, p. 907), and to note the comments on radiation treatment of this condition by Dr. Curtis Webb (December 3rd, p. 1053). It is well recognized that the more highly specialized tissues like the ovary, the thyroid, and the thymus are very amenable to radiation treatment. Wintz of Erlangen gives the dosage for ovarian tissue as 34 per cent of the unit skin dose, and we do know that when this dose is applied the ovaries cease to function and a menopause is produced. I have no doubt that the prostate also responds to its dose of choice, although this dose has not been worked out.

There is, however, another factor in addition to a quantitative dosage, and that is a qualitative dosage. When the science of radiology becomes more exact the question of this qualitative factor, or the wave-length of the ray employed, will play a greater part. I have been investigating recently the treatment both by radium and x-ray therapy of a number of cases of enlarged prostate, mostly of the simple adenomatous type. In the treatment by radium the sphincter was dilated under an anaesthetic, and a heavily filtered radium plaque inserted per rectum and placed in contact with the enlarged prostate. The results were quite satisfactory. I also used deep therapy,

giving one penneil and two suprapubic ports of entry, directed towards the prostate and aiming at a depth dose of 40 per cent unit skin dose. The results here were not so satisfactory.

More recently I have been treating these cases by superficial therapy, giving multiple small doses, about twelve in all, over a period of six weeks, and directed through one rectal port of entry. The results by this method have been the most encouraging of all. Out of eleven cases treated in private one only failed to respond, and in this case complete incontinence of urine was present, which was not due to the prostatic condition. All these patients were referred to me by surgeons on account of the mid-visibility of operation from systemic causes. Records of the frequency of micturition and the number of times that the catheter was used were kept by the patient. In the ten cases mentioned where a catheter was used this was dispensed with, and the frequency in all cases dropped from six to eight times a night to a complete undisturbed night. The prostate was examined at frequent intervals and the reduction noted. One patient returned after a year's interval on account of his having to use the catheter. About six exposures were given, and the catheter has now been dispensed with. The dosage employed was about one Holzknecht unit filtered through three millimetres of aluminium. The last four applications were filtered through four millimetres of aluminium. A 16-in. coil and a standard Coolidge tube were used, with a spark-gap of about 65 in. and two milliamperes of current.

The only explanation that I can offer of these results is that with these repeated small doses and a medium hard ray I have, as it were, approximated the prostatic ray and dose of choice. In all these cases the testicles were not protected, so that the margin of the field affected these, and the giving of this partial castration dose helped the reduction of the prostate.—I am, etc.,

Hull, Dec. 10th.

J. E. BARNES

## PROPHYLAXIS AND CURE OF COLDS

SIR—"Never a scientist has dared to hint that he has discovered a cure for the common cold." These words occur in a recent leader in the *Morning Post* on "November colds", and the statement I take to be true in substance and in fact. Nor have we as yet a settled opinion as to the value of prophylactic antiserumal vaccines. Partially controlled experiments in schools have been published from time to time. On the whole these tend to throw doubt on the efficacy of this method of prevention. All of them apparently are open to the objection that the majority of the individuals inoculated have volunteered, and the treated class, in consequence, consists mainly of those who suffer frequently from catarrhs due to infected respiratory passages. It is agreed, I think, that the chronic carrier of catarrh germs is not the best subject for prophylactic inoculation, since not only may the inoculation provoke a cold, but it usually fails to clear away the patient's own microbes, for which purpose an autogenous vaccine must first be administered. None the less, many people assert with conviction that in their case prophylactic catarrh vaccine has prevented recurring colds. To obtain useful statistics where numbers are small, only those individuals should take part whose nasal mucous membrane has been found sterile, or has been so rendered by autogenous vaccines.

It is fairly certain that prophylactic injections act by raising the blood immunity, whereas theoretically the first requirement of cold prophylaxis is to render the mucous membrane immune. This, if practicable, together with an enhanced blood immunity, should provide the ideal cold prophylaxis.

Besiedky's remarkable experiments on the local production of immunity to influenza in the skin of guinea pigs, followed by the application of the same principle in the treatment of local infections such as furunculosis, acne, and colitis, led some bacteriologists to make use of this principle in the prevention of colds. At the present time there is quite a number of antiserumal sprays vaccines on the market, either as extracts (according to Besiedky) or combined with bile, glycerin, or other diluent with a view to assisting penetration into the mucous membrane.

I have not been able to find any published reports or the results, therefore I thought my experience with the method might be worth giving. In general I have found that with a vaccine of the correct strength benefit accrues, but if the strength is too strong a child may be provoked just as with prophylactic injections. After a good deal of experiment, which established the above two points, I settled down to a routine method as follows:

A highly polyvalent vaccine of various catarrhs of the eye of a strength of 500 million per cubic centimetre diluted with simple 0.5 per cent phenol in normal saline is used for adults, and half that strength for infants. It is given regularly once a week, and, in addition, whenever the catarrhs or early catarrh are experienced.

The spray (or the Atlas type) is used intelligently so as to cover the whole ground. The next I do not plugging by the nasal end of the spray, but I pass the left so that the vaccine can be sniffed up as the bulb is squeezed. This is done two times to each nostril. Afterwards the mouth and throat are sprayed whilst the breath is sharply drawn—expiration takes place through the nose. Thus all the upper passages are reached. The results have been very good, not only in preventing colds, but also in curing a cold even in the most acute stage. My experience has now lasted over some two years and I feel able to assert with a good deal of confidence that the above method, faithfully carried out, in combination with prophylactic anti-catarth inoculations, will be successful in a large proportion of all cases. It has one great advantage—namely, that the actual spraying can be carried out by the patient himself—I am, etc.,

H WARREN CROWE

London W1 Nov 25th

#### TUBERCULOUS LESIONS FOLLOWING INJECTION OF PITUITARY EXTRACT

SIR—Within the last three years we have had four cases of mild tuberculous lesions of the lung which we have every reason to believe followed injections of pituitary extract.

After the first two cases one of us got in touch with the makers of this drug, who told us euphorically that it was quite impossible for the living tubercle to exist in the extract. Now that two more cases have come under our care we should like to hear whether other people have had similar experience as if there are a number of such cases the matter should be taken up by the various firms who are making this drug.

In two of these cases the lungs have been excised and sections showed undoubted tuberculous lesions. We are, etc.,

MALCOLM DONALDSON, FRCS  
C S LYNE ROBERTS, FRCS

London W1 Dec 6th

#### ERGOSTEROL VITAMIN D, AND RICKETS

SIR—Professor Wynne's letter in your issue of November 26th recalls very clearly the respective theories as to the etiology of rickets submitted by Professor Mellanby and his co-workers on the one hand and by the Glasgow school on the other hand some years ago before the facts as to the influence of ultra-violet light on this disease became generally known. It is however with the concluding paragraph of Professor Wynne's letter that I am chiefly concerned, as it raises a question of very great importance in the field of public health at the present time—namely, whether the prevention of rickets should be tackled by public health authorities exclusively along the lines of instruction in diet and provision of cod liver oil or whether artificial sunlight clinics should be developed as part of a public health policy. As one who has experimented with both of these lines of action in children welfare centres in a northern town may I be permitted to emphasize the great value of the latter?

In my experience far quicker and more constant results in the cure of active rickets with improvement of general health are obtained by the use of ultra violet light than by instruction in diet and provision of cod liver oil, and I am of opinion that exposure of the

skin of infants to light and air should be our primary means of preventing rickets. If the prevention of rickets is intended to come primarily by absorption of vitamin D through the alimentary tract why is there so much rickets in breast-fed babies? On the other hand many breast-fed babies who have never had cod liver oil escape rickets, and do not these belong mainly to the classes who take every opportunity during the summer of freely exposing their children's bodies to light and air? Does it not seem from the facts that nature intended us to absorb vitamin D primarily from our skins?

The great value of artificial sunlight clinics, from the public health point of view is not only that they marvellously restore rachitic infants to health, but that they draw attention to the vital necessity of regular and repeated doses of sunlight on the naked body for the healthy rearing of infants.

This, I submit, should be regarded as a factor of primary importance in the prevention of rickets even in this climate. In practice every antirachitic influence that can be utilized is often required for success. An antirachitic diet of course should be our aim for all children and cod liver oil and its substitutes are of great assistance although their application is quite often limited. But if we recognize the prime importance of the skin route for the absorption of vitamin D with maintenance of general health, we shall concentrate upon teaching people to make the most of our sunlight and we shall consider the expense of the public provision of artificial sunlight clinics justified—I am, etc.,

#### THE PHYSIOLOGY OF DEFECATION

SIR—It seems evident that the habit of constipation has been evolved as an adaptation to the necessities of civilization. A cow may derectate whenever and wherever she pleases. A monkey with his arboreal life may do almost the same though possibly he has developed an instinct to retire to the lower branches for defaecation so as not to inconvenience his fellows. But when primitive man took to gregarious life in caves or huts it was necessary to deter defaecation and the individuals who could not do so must have been eliminated as unfit. As civilization became more complex a further elimination must have occurred. Think of the primitive conditions when there were no conveniences, houses, and when the retirement to a "draught-house" or privy was a thing to be avoided as long as possible! And think of the long journeys, with inadequate accommodation at the stopping places!

Nowadays the man who has two or three evacuations a day though in consequence he may enjoy better health and longer life, has certain disadvantages to put up with which some persons find serious for his call to defaecation is apt to occur in the midst of a social function or a journey and (far too often) in the night—I am, etc.,

Cambridge Dec 14th

F J ALLAN

SIR—The very great importance of the correct understanding of this subject prompts me to suggest that it is the greatest pity that the views of Sir Arbuthnot Lane and his school and those of Dr A F Hurst cannot be compared and reconciled for I know that these two schools are in possession of knowledge or, rather insight into the physiology of the colon that can hardly be aided to exist academically, and is therefore not available to the profession generally.

I was years since deeply indebted to Sir A Lane for his guidance in the study of the physiology and pathology of the abdomen but I am also largely indebted to Dr Hurst for drawing my attention (through his book on constipation) to the wonderful observations of O'Brien after years of study I came to these conclusions, briefly stated:

1 That the mass peristalsis observed by X rays to occur in the colon three or four times in the twenty four hours was the natural, but in civilized people a futile effort at defaecation

and that, therefore, repeated defecation during twenty four hours is the true physiological state

2 That, therefore, "normal" people were living unphysiologically

3 That—most important of all, it seems to me—the primary lesion (or the primary stage) in the development of chronic intestinal disease was residual faeces in the pelvic colon

It is to this condition that I wish especially to draw attention. Here is a grave and most common pathological condition which is unrecognized by the profession at large. So little is it known that it is commonly described, when seen by a ray, as "faeces in the rectum."

I have drawn the attention of Sir A. Lane and others to this really serious error, which occurs in authoritative books on constipation and the radiology of the abdomen (I can give exact references if required). I drew attention to this grave pathological condition in my pamphlet *A Study of Intestinal Stasis* (1922, J. Bale, Sons and Danielsson), which was favourably reviewed in the *BRITISH MEDICAL JOURNAL* and the *Indian Medical Gazette* and elsewhere. I there also appealed for the serious consideration as to whether our "normal" was really a truly physiological standard. Dr. A. C. Jordan (*BRITISH MEDICAL JOURNAL*, December 10th, p. 1120) evidently agrees with me that it is not.

Until this question is examined, academically and clinically, we shall not make progress in the prevention and control of acute and chronic intestinal diseases. On the other hand, let it be once realized that the chronic presence of residual faeces in the pelvic colon is as definite a disease as, say, pyelitis or residual retention of urine in the bladder, or empyema in any cavity of the body, and we shall go ahead.

At present, in routine x-ray reports on the alimentary tract, this gross lesion is commonly ignored and overlooked. Physicians should ask for a picture of the pelvis taken immediately or shortly after defaecation, whatever hour this may occur after the opaque meal has been given—I am, etc.,

London Dec 12th

JAMES C. WITT

### THE PROBLEM OF MENTAL DEFICIENCY

SIR,—A very important report has just been issued by the administrator of the Besford Court Catholic Mental Welfare Hospital for Children. So retrograde are the views expressed that I venture to call attention to them through the columns of the *JOURNAL*.

It is difficult in the short space I can expect from you to comment adequately on all the points raised. I will deal with the principal one, the mental deficiency problem viewed in the light of Catholic philosophy. The author claims that four inherent rights of humanity have been assailed by modern social reformers. They are (1) the right to live, (2) the right to bodily integrity, (3) the right to freedom, (4) the right to marriage.

(1) No one disputes this. The lethal chamber for aments is not advocated by any social reformer. The point therefore does not need discussion.

(2) The author condemns, on religious grounds, the sterilization of defectives. It is, he says, a brutal assault on innocent and defenceless members of society. Although I am a very strong opponent of sterilization I cannot for one moment agree with the reason given against it. There are other and much better ones. If sterilization would diminish the sexual crimes of defectives, if it would do anything to help to cure the state of mental deficiency, if it would in any way lessen the antisocial tendencies of the aments or in any way assist in solving the problem of our defective population, I would whole-heartedly support it. But sterilization does one thing, and one thing only, and that is prevent the production of children. It does not alter or improve the mental condition. It does not diminish sexual power or desire, and therefore it does not lessen the risk of sexual offences or of the propagation of venereal disease. It does not make the defective criminal into an honest man. It does not make the unemployable ament into a useful citizen. It does not make the immoral feeble-minded into a moral being. It does not enable the pauper or vagrant defective to earn his own living. Therefore it leaves exactly the same necessity (with the single

exception of the question of propagation) for constant and perpetual supervision as before the operation was carried out. If sterilization must of necessity be followed by segregation (and if we are properly to control the mentally defectives, segregation is essentially what benefit is it to sterilize at all?)

(3) This right of freedom, if conceded, would entail enormous harm on the general community. The antisocial propensities of the mentally defectives (as evidenced by crime, sexual outbreaks, pauperism, vagrancy, alcoholism, and so on) must be controlled. This is best attained by segregating the aments in special institutions, where, under proper control and care, they live happy and contented lives, yet cannot inflict harm on the community. Their injurious tendencies are kept in bounds, and cannot cause much mischief or suffering to their fellow creatures.

(4) It is generally agreed, I think, by those who have made a study of the subject, that the offspring of two mentally defectives is *always* a mentally defective, the offspring of a mentally defective and a normal is *generally* defective. This fact by itself justifies the conclusion that in no circumstances should a mentally defective be allowed to marry and propagate. The problem is serious enough as it is. By deliberately encouraging the further production of aments it would become far more difficult.

With every admiration for the well meant efforts of the institution, it is impossible to accept them as a forward contribution to the solution of the important question of the management of the feeble-minded. It is a very distinctly retrograde movement. The present-day attitude of sociologists in this matter cannot truthfully be called "a regression towards pragmatism." The efforts being made for the efficient and adequate treatment of this sociological question are sane, sensible, and humane. They at least have a chance of lessening the number of the antisocial elements in our population—I am, etc.,

Hove, Nov. 18th

L. A. PARRIS, F.R.C.S.

### CONTRIBUTORY SCHEMES FOR HOSPITALS

SIR,—The success of contributory schemes in raising money is due to the demand for specialist advice and a nursing home, two necessities which only the very poor or the fairly rich can obtain.

The fruits of the schemes are (1) Poor people are crowded out of hospitals. (2) The general practitioner loses his patients. (3) The specialist, more especially if not on the staff, also loses patients.

The remedies are (1) Contributory schemes should be on such a scale that they can pay establishment charges, etc., in order that the necessary enlargements may be made. (2) The general practitioner should be able to use the hospital as a nursing home. Of course it will be said that this is impracticable, but general practitioners follow their cases in private nursing homes. Poor law infirmaries might be turned into municipal nursing homes and the panel doctor treat his cases there. (3) Provision from the fund should be made for payment of specialist fees as in the ophthalmic benefit scheme.

Your correspondent Dr. Fothergill (November 12th, p. 899) writes of specialists not on the staff of a hospital. All specialists and general practitioners should have an opportunity of serving on the staff. The above remarks do not apply to teaching hospitals—I am, etc.,

Southsea, Nov. 17th

F. C. B. GITTINGS, M.D. Lond.

### THE THERAPEUTIC ACTION OF CALCIUM SALTS

SIR,—Dr. Priest's communication to the *JOURNAL* (November 19th, p. 958) raises some interesting points. The first is the greater therapeutic value of calcium in the colloidal than the crystalline state. In the discussion on calcium therapy (October 29th, p. 777) most of the speakers referred to the use of calcium in the crystalline form, solutions of calcium salts being discarded as calcium ions. As there is a carefully maintained balance of calcium ions in the blood, it is unlikely that medication with calcium ions will do much to upset this balance more than a very short time.

## Medical News.

**THE** late Mr W Thelwall Thomas of Liverpool who died in September last has left estate of the value of £118 388, with net personality £109 759. He bequeathed £5 000 each to the University of Liverpool to endow a fellowship in surgical pathology, the Royal College of Surgeons of England and the Royal Medical Benevolent Fund for pensions for medical men and their widows. He has also given £1 000 to the Liverpool Medical Institution for the annual purchase of books of reference or journals. He directed that his house in Rodney Street should be used as chambers for medical men so long as the executors shall think fit the portrait in oils of himself he bequeathed to the University of Liverpool.

**MR HORACE H REW** assistant secretary of the Conjoint Board in England has succeeded as secretary Mr I G Hullett whose resignation took effect on December 5th.

**THE** house of the Royal Society of Medicine will be closed from Friday, December 23rd, to Tuesday, December 27th, both days included.

**AT** the meeting of the Royal Microscopical Society to be held at 20 Hanover Square, W 1 on Wednesday, December 21st at 8 p.m. papers will be read by Dr W J Elford on the principles of ultra filtration and by Dr G C Sansom on the origin of giant cells in the placenta. The annual meeting of the society will be held on January 18th when Dr James A Murray F.R.S. will deliver his presidential address.

**A** POST GRADUATE course on diseases of the nervous system will be held at the National Hospital, Queen Square, London, W C 1, from January 30th to March 23rd 1923. The course will consist of clinical lectures and demonstrations teaching in the out patient department and pathological lectures and demonstrations. The fee will be £5 5s. A course of lectures on the anatomy and physiology of the nervous system will be arranged if there are sufficient applicants. fee £2 2s. Clinical demonstrations of methods of diagnosis in diseases of the nervous system will also be given. fee £2 2s.

**AS** announced in our advertisement pages the Grocers Company with the object of encouraging original research in sanitary science is offering scholarships of £300 a year each, together with an allowance to meet the cost of apparatus and other expenses in connection with the work. Applications forms can be obtained from the clerk to the Grocers' Company, Grocers' Hall, E C 2 to whom they must be returned before the end of April.

**THE** Old Epsonian Club held its fiftieth annual meeting and dinner on December 8th. Sir Cecil Armitage the new president of the club in proposing Floreat Epsonian related how he entered St George's Hospital and studied materia medica, but on reaching bones decided to join the West African Colonial Service and through the first aid he learnt at the hospital gained the respect and affection of the natives. He said that the colonial service offered many openings to medical men especially in West Africa some times leading as in the case of Sir William McGregor, to governorship. The headmaster Mr Powell in replying described the efforts now being made to raise the age of entry at the school to 12 years thereby bringing Epson into line with the large public schools. The boys of public school age now numbered 329 instead of 234 and shortly should be 400. Mr Powell gave an account of the successes achieved in scholarships the classrooms and sport. Dr H F Ealand, in a humorous speech proposed the health of the guests. In reply the Right Hon W Ormsby Gore parliamentary under secretary to the Colonial Office twitted Dr Ealand with inaccuracies, urged the advantages of the colonial service as a career and said that owing to the doctors' West Africa was no longer the white man's grave. The dinner was very successful and the attendance was said to be the largest ever attained.

**OLD** St Bartholomew's men will be glad to know that a new edition of *Round the Fountain* (with illustrations) is due to appear before Christmas. Besides the paper covered edition at 3s. 6d. a limited number of copies will be printed on superior paper in cloth binding at 7s. 6d.

**DR W HENDERSON DAVISON** O.B.E. barrister at law at present acting medical officer of health for Birmingham has been appointed coroner for the city of Birmingham at a salary of £1 250 a year in succession to the late Mr Isaac Bradley. At a meeting of the Public Health Committee of the corporation of Birmingham on December 9th a resolution appreciative of Dr Davison's services was adopted.

**SOME** more cases of the disease described by Drs Olmer Boinet and Picri to the Académie de Médecine and referred to in the paragraph entitled *Brill's disease* at Marseilles published a fortnight ago were reported on November 15th to the Académie de Médecine by Drs Plazy, Marcon, and

this case to the notice of the authorities concerned and still hoped that something might be done. Brigadier General Brown asked the Minister to consider the question of placing a mark on tuberculin tested milk which had been properly inspected. No answer was given.

**THE** *Ill-rite*—On December 13th Mr G Locker Lampson told Lieutenant Commander Kenworthy that the Government had decided not to ratify the convention against gas and baculo logical warfare agreed upon at Geneva until all other important Powers had ratified its protocol or had signed their intention of doing so.

**THE** *Electric Medical Officers of Health*—On December 12th Sir K Wood replying to Dr Vernon Davis said that there were 118 non county boroughs and 182 urban districts in England and Wales with full time medical officers of health.

**Votes in Brief**

It is not the practice of the Civil Service Commissioners to examine the physical qualification of persons who apply for admission to civil service examinations. Their physical eligibility for appointment is investigated in the event of their success and the Government cannot consider the suggestion of a prior medical examination at the candidate's expense.

**A**sked whether the Government would now ratify the International Labour Office Convention on Maternity Protection, Sir Arthur Steel Maitland said this country already had in force a policy aiming at the same results, and the Government could not to the adoption of the specific proposals of the Convention would lead to administrative difficulties.

**Information** showing the number of former patients of sanatoriums who had become chargeable to the guardians is not available.

**The** Minister of Education is raising one of the medical officers of the Board of Education to make a special inquiry into the physical state of children in South Wales.

**The** Ministry of Transport rules that grants could not properly be made from the Road Fund to enable hospitals to meet the extra costs resulting from the number of motoring accidents.

## The Services

## NO 1, STATIONARY HOSPITAL

**THE** eightieth annual dinner of the No 1 Stationary Hospital was held at the Trocadero Restaurant, London, on December 9th. Lieut Colonel J R Harper C.B.E. who was in the chair proposed briefly the toast of The Hospital and in reply Colonel J S Warraek contributed a few anecdotes which provoked a brisk interchange of pleasant and humorous reminiscences ranging over the four years' activity of the hospital on the French coast. Numerous letters had been received from members of the staff now in foreign countries. A hearty vote of thanks was accorded to Dr H L Tidy the organizer of the dinner.

## DEATHS IN THE SERVICES

**DR** **SAMUEL KEYS** R.N. (ret.) died at Kingstown, Co. Dublin, on November 7th. He was educated in the school of the Irish College of Surgeons, and took the L.R.C.S.I. in 1875. He entered the L.R.C.Q.P. in 1876 and the M.K.Q.C.P. in 1884. He entered the navy in 1878 and became fleet surgeon in 1889 and retired in July 1903.

**Colonel William Edward Riordan** Army Medical Service (ret.) died at Southsea on November 11th, aged 87. He received his medical education in the school of the Irish College of Surgeons and took the L.R.C.S.I. in 1863 and the L.R.C.Q.P. in the following year. Entering the army as assistant surgeon in September 1864 he attained the rank of colonel in 1895 and retired in 1900. In the old regimental days he was medical officer in the Royal Artillery. He served in the Egyptian war of 1882 receiving the medal and the Khedive's bronze star and in the Sudan campaign of 1885 at Suakin gaining a clasp. He was the author of a *Manual for the Army Medical Service*.

**Inspector General Harry Hadlow** R.N. (ret.) died at Southsea on November 30th, at the advanced age of 91. He took the L.S.A. in 1857, seventy years ago, and the M.R.C.S. in 1859. Entering the navy soon after as assistant surgeon he attained the rank of deputy inspector-general on May 3rd 1883. He retired with an honorary stipend in rank as inspector-general on Mar 7th 1894. He received the Sir Gilbert Blane medal for his journal of practice on board ship. As assistant surgeon he was in the traits of Simons etc. present at the attack on the batteries on HMS *Cerberus* in Japan, from September 5th to 8th 1864. His active service therefore was at a period prior to the revolution in Japan which brought the Mikado to the headship of that country—a actual as well as nominal ruler.

**Further** details have now reached us regarding the career of Lieut Colonel Lewis Cameron on whom an obituary notice appeared on October 23rd (p. 800). While civil surgeon of Backerganj a storm wave swept the district killed large numbers of people and threatened the remainder with cholera. Colonel Cameron placed considerable time and money in travelling by boat from place to place in order to treat those in need and prevent further disaster. During his service in Rajshahi he was for 12 years in control of the central prison and at the time of his retirement was offered an inspectorship of jails.

Carboni. The onset was sudden, with headache, lassitude, constipation, and meteorism. The spleen was enlarged, 50 per cent of the cases. The rash was discrete and either morbilliform or in lenticular rose spots. Occasionally it became purpuric. In some cases there was a buccopharyngeal rash, or the conjunctivae were injected. None of these patients died. All the cases occurred between the months of March and October. The patients came from ships or from the neighbourhood of the port, none were venimous, and the authors were inclined to attribute the source of infection to rats or mice. As noted in our original paragraph and emphasized in Dr Goodall's letter last week, the disease would appear to be a mild form of typhus, or, as Plazy and his colleagues would call it, "benign endemic typhus (Brill's disease)".

THERE has been more small pox during the past summer in the United States than in the corresponding periods of 1926 or 1925, the figures given by 37 States for thirteen weeks being as follows: 1927, 2,900 cases, 1926, 2,400 cases, 1925, 2,000 cases. The virulent type, however, has not appeared in the United States this year, and very few deaths from the disease have been reported. Poliomyelitis also has been more prevalent than in either of the two preceding years: 37 States reported 4,000 cases for the thirteen weeks in 1927, 1,100 in 1926, and 3,200 in 1925.

## Letters, Notes, and Answers.

All communications in regard to editorial business should be addressed to the **EDITOR, British Medical Journal, British Medical Association House, Tavistock Square, W.C.1**

**ORIGINAL ARTICLES** and **LETTERS** forwarded for publication are understood to be offered to the **BRITISH MEDICAL JOURNAL** alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

## QUERIES AND ANSWERS

### TRIALMENT OF SYPHILIS

"K" asks for advice in the treatment of a stubborn case of syphilis, or of proctitis, a living child in the following case. The patient has had three dead born full term babies one being an anencephalic monster. The disease is of seven years' duration. For three years he injected her intravenously and intramuscularly with novarsenobion and in addition gave full doses of mercury and potassium iodide. This year a colleague took charge of her and gave her eight injections of salvarsan and massive doses of mercury and potassium iodide. She aborted in a month and her blood to day gives a Wassermann reaction (plus four). She is very stout and apparently in excellent health. Her husband responded to treatment very readily, and his blood gives a negative Wassermann reaction.

### INCOME TAX

#### Motor Car Allowance

F.C. inquires with regard to a sequence of car transactions. It should be remembered that the cost of replacement allowance is not given in respect of the loss on the car displaced but as representing the appropriate part of the expenditure incurred on the new car. Thus the net cost of the second car bought in 1914—that is £537—£110=£427—should have been the amount allowable in respect of the 1914 transaction and so on. The question of capital improvement is complicated by two factors—first the fact that a saloon car was used between 1914 and 1922 and secondly by the full market prices between 1922 and 1926. If the last two cars are taken by themselves the inspector of taxes is right in objecting to the 'saloon' basis of cost, but seeing that a saloon car was in use to 1922 we think he would probably drop the objection if that fact is emphasized. The

proposed future depreciation allowance of 15 per cent is not uncommon. The decision on the matter rests with the Commissioners, to whom an appeal would be made. They might take into account the fact that to the extent to which it is insufficient an obsolescence claim will normally put the taxpayer right when the car is renewed.

### Change in Partnership Cash Basis

"APEX" explains that as from January 1st 1928 his share in the practice will be increased from one third to two fifths. What effect on income tax will result from (1) including, and (2) excluding outstanding book debts in the valuation to be placed on the additional share purchased?

The amount of the income tax paid by "APEX" should not be affected by the choice arrived at, the cash basis method is only an approximate method of calculating the true liability, which is on the basis of the value of gross earnings. If the firm as reconstructed adhere to the cash basis system for the future, as we assume they intend to do, the tax payable by "APEX" will bear a close ratio to his net cash receipts from the practice. It is true that he will have bought some of those receipts but, on the other hand, he will be accounting for income tax (as is legally correct) on other income which has been earned but has not actually been received.

### Change in Membership of Firm Cash Basis

"C" and "L" were in partnership to July 1st, 1926, when they were joined by "H," formerly their assistant. The assessment for 1927-28 is based on the cash receipts of the practice for the year to 1926 less the expenses of the three partners including, presumably, "H's" salary for the six months to July 1st 1926, but the fractional division of the subsequent profits does not apply to fees earned before that date.

It is, of course, clear that "H's" share of the tax will exceed what he would have to pay on the basis of his share of the cash receipts of the year, but this is correct, because, as a commencing partner, such receipts do not adequately indicate his income tax liability. The figures supplied by the inspector of taxes seem to us sufficiently correct in the special circumstances, the only alternative is for the firm, as a whole, to disband the cash basis for 1927-28 and future years and base their returns on the value of the fees booked instead of the cash received. "H" may perhaps be unfortunate at the moment if, as is possible of course, the cash receipts for the six months prior to his entering the partnership were abnormal in which case he will be helping to pay tax on the harvesting of his partner's past earnings.

## LETTERS, NOTES, ETC

### PIREXIA WITHOUT VISCERAL SIGNS

DR SUNDARA RAJAN (Coimbatore, South India) writes to express his interest in Dr Franklin's note (*JOURNAL*, August 27th p. 350) on pyrexia without visceral signs, which he thought might be due to slight intestinal influenza. Dr Rajan states that he has seen ten such cases within three years. The patients had a sudden rise of temperature unaccompanied by pain, but with a little cough, for which no cause could be found in throat or lungs. The tongue was furled and very often there was slight constipation. When this was relieved and the patient put on a diaphoretic mixture the pyrexia still persisted for three or four days. Even mixtures containing sodium salicylate did not influence the fever.

### PREMATURE RUPTURE OF THE MEMBRANES

DR J. S. PRARSL (Plymouth) refers to the comments of A. Mayer and E. Frey (*Lancet*, December 3rd, paras 529 and 530) on the increasing number of cases of premature rupture of the membranes. Dr Prarsel has noted also frequent reports of such cases in the **BRITISH MEDICAL JOURNAL**, and raises the question whether this premature rupture, if it occurs, can be classed as a definite post-war condition. He remarks, however, that it is used to be a common experience, both before and during the war, to be told erroneously on arrival at a midwifery case that the membranes had broken. The mistake arose from the escape of the "forewaters" in hydrotome gravid woman, premature rupture of the membranes being quite a rare event.

### CORRECTION

In our report of the discussion at the Medical Society of London on late results of operation for carcinoma of the breast published last week the initials of Mr A. J. Walton (page 1036) were incorrectly given.

### VACANCIES

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 43, 46 and 48 of our advertisement columns and advertisements as to partnerships, assistantships, and locumtenencies at pages 44 and 45. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 236.

## A DISCUSSION

ON

THERAPEUTIC MODIFICATION OF THE DIET  
IN INFANCY

BY

HILTON C. CAMERON, M.D., CAMBRIDGE, I.P.C.P. LOND.,  
F.R.C.P. and Physician-in-Charge of Department Diseases of  
Children, Guy's Hospital

DEALING upon the subject of infant feeding seldom arouse profitable discussion. As a rule, the aim is to make clear only the difficulty or reconciling the views of those who might be supposed to speak with authority. Therefore, in the first place, I would ask the question: Whom has this difficult and complex subject? Why is it that in this subject, on the importance of which all are agreed, opinion has remained so fluid and so little that is solid and concrete has crystallized out from it? Why is it that in practice we still encounter, on the one hand, a frozen view among a host of proprietary foods for one which may run up to the promises of all or on the other hand, a too rigid adhesion to some one system of feeding despite the persistence of symptoms?

*Difficulties Inherent in the Subject*

It is obvious that some of the difficulties with which we have to contend are inherent in the subject itself. In the practice of infant feeding the data are difficult to interpret for two reasons. On the one hand it is mercifully the nature of the child to wax and wane strong and thus upon a very great diversity of dietetic prescriptions. Yet the prescriber of each diet is prone to claim this most vital happening as evidence of success and as proof of the virtues of his prescription. On the other hand the human infant is of so sensitive a nervous organization that a great variety of adverse circumstances are capable of producing ill effects upon its health—effects which almost always manifest themselves in gastro-intestinal and nutritional disturbance.

The infant has but one function highly developed that of the digestion and absorption of food. So hypertrophied a function is necessarily unstable and in the absence of other functions capable of manifesting symptoms of derangement disorders of very different natures are apt to show themselves in the guise of digestive and nutritional disturbance. Thus intercurrent infective diseases, great variations in the atmospheric temperature or humidity, extreme restlessness from timid or uncertain handling or from overstimulation on inco-ordinate and ineffective suction with its phagor, individual inherited idiosyncrasies against certain constituents of the food are each and all capable of so lowering the tolerance for a diet in itself quite unobjectionable that severe dyspepsia may result. Because of the action of one or other of these adverse influences many dietetic prescriptions in themselves admirable are apt to fall into disrepute and to bear the blame of a disturbance of which they have not primarily been the cause. On the other hand since these influences are more often than not transitory in their action many dietetic recipes tried at the moment of recovery, bear off the credit for that recovery which was in fact quite unconnected with their use.

Thus difficulties are inherent in the study of the infant and of its diet but in this country at the present time there are other difficulties with which we have to contend and which are responsible in part for the confusion which surrounds the subject. I will briefly refer to three only.

*The Neglect of the Study of Pediatrics in Universities and Medical Schools*

In medical schools and universities too little attention is paid to the scientific study of the child. The subject is regarded as a specialty. It is regarded as a specialty for recognition among the conflicting claims of otolaryngology,

orthopedics and even proctology. We may be sure that only when it has been elevated to the rank of a subject of the first importance, and takes its place with medicine and midwifery as one of the pillars of the final examination can we hope to find the profession as a whole equipped as we would have it equipped to deal with so all important a branch of general practice. Operative surgery on the other hand, which occupies to-day so large a part of the student's time and attention belongs rightly to the specialties. Its practice is a matter for post-graduate rather than undergraduate study and its technique can only be usefully acquired by the special training of some of those who have already received a medical education. The dearth of professional chairs in pediatrics in this country is both symptomatic of and productive of the widespread neglect of the subject.

*Detrimental Effect of the Advertisements of Proprietary Foods*

To the lay mind the proof of the pudding is in the eating. Digestive derangement however caused is taken as indicating that the particular diet adopted is responsible for the disturbance and a change is demanded. One food after another may be tried in an unmethodical search for something which suits. The numerous advertisements of proprietary foods are cleverly designed to play upon the anxieties of the mother. Their effect in producing this constant demand for change and in increasing our difficulties is not lightly to be set aside. Nothing is more amazing to-day than the success of advertisement in a population trained to read but not to reason. The latest device is the advertisement in the form of a Socratic dialogue—hitherto confined to the vendors of cheap furniture—under a picture of the kindly doctor with his arm resting reassuringly on the shoulder of the distressed young mother, while he extols the virtues of the food, and she dutifully undertakes to follow such good advice.

These foods are to some extent the raw materials of the physician's art. Their virtue lies in the uses to which they are put not in their composition. Many owe their origin to successful prescriptions in the past for particular types of disturbance. Commercially however there is little profit to be made by putting on the market a diet for sick infants only hedged by restrictions and indications for and against its use. It is more profitable to make the claim of universal applicability based on selected cases which have undoubtedly thrived by their use.

*III Effects due to Misunderstanding of Propaganda for Infant Welfare*

The appreciation of the disastrous effect of these repeated and injudicious changes of diet in the dyspeptic disturbances of infancy has led some to go to the opposite extreme and to maintain that by a rigid adhesion to some particular formula or scheme of feeding success can always be attained at least in what is called a "well baby." This is the attitude which has been associated to take one well known example with the name of Sir Frederick Truby King. He says in effect "Give me a healthy baby and I will show you how to keep it healthy." It were to ask him he would say "With sick infants I have nothing to do. My work is preventive not curative." He rightly regards the preparation and supervision of the diet of the healthy infant as falling within the province of the educated mother or children's nurse supervised and instructed, it need be by the trained nurse or infant welfare worker. No one can fail to admire the enthusiasm which he has thrown into his work and the energy with which he has conducted his extensive propaganda among mothers and nurses. But propaganda upon matters of health is by no means free from danger to the public. There is indeed, at the present time an attempt on the part of certain medical men to enlighten the services of the lay press in bringing medical knowledge to the notice of the public. Those who oppose the suggestion are all too fearful of its effects. They will point to certain unhappy results which have followed on the propaganda for infant welfare. No one branch of medicine has been so subjected to this process of popularization. For popular consumption propaganda must be so simplified that the truth is

The foregoing paper of a discussion in the Section of Diseases of Children at the Annual Meeting of the British Medical Association in Edinburgh, 1927.

almost squeezed out of it in the process. An outline, a mere diagram, is all that can be depicted, without light or shade, without degrees of emphasis, and without consideration of exceptions or variation. Hence we find that the successful propagandist is seldom himself expert. Late in life a surgeon, supreme in his art, turns dietitian, or an asylum superintendent devotes his later years to the standardization of infant feeding.

All standardization is detrimental to the progress of medicine, although it immensely simplifies elementary teaching. The effect of standardization in this instance, although certainly not its aim, has been to tend to leave the doctor out as one no longer needed. The public has become confused. It hears the Tinby King or some other "system" of feeding extolled as giving admirable results. Why should these great benefits be confined to healthy infants? The mother of some ailing child demands that it, too, should share in them. And so it comes about that ailing infants are admitted to institutions which were designed only for preventive work, and that mothers and nurses come to regard the standard diet—which I should look on much as a sighting shot, to be persisted in only if successful—as conferring health on all dyspeptic infants.

If it were possible to feed all infants, healthy or sick, in the same way, it would indeed be true that the subject could have no possible interest for medical men. The nurse, trained in the preparation of the particular diet, would then rightly take charge. The routine dietetic treatment, known beforehand, is then all that is required, beyond that skilled nursing and handling which every baby needs, and which is, in truth, the replaceable and all-important contribution of the trained nurse. Indeed, under a standardized system it is not necessary before giving advice to see the infant at all, or to make any examination of it. In one of the largest institutions for infant welfare it is considered possible to manage the whole business by letter. The nation conducts a consultation department known as "Better Babies by Post." From all over the country mothers write describing the symptoms from which their babies are suffering, and question and answer are published in the lay press. The child may be overfed or underfed, it may have pectus, or it may be suffering from injury to its medulla oblongata at birth—no one knows, but the advice by post, a little stereotyped perhaps, but simple and legible, is always to be obtained. Such happenings bring discredit upon a subject the welfare of which all of us have very much at heart.

We need, I think, above all the elevation of pediatrics, as the most truly educative of all subjects, as well as one of the most important in practice and for the service of the State, to a more important place in the curriculum. I would welcome, too, some restriction on the trade in proprietary infant foods, and in the character of their advertisements. The difficulties of the infant welfare movement will right themselves in time. In time the public will learn not to confound sensible advice on the care and diet of a healthy infant with the therapeutics of the sick.

#### *Therapeutic Modification of the Diet*

In the last twenty years much progress has been made in the attempt, based upon the study of the etiology of particular symptoms, to devise modifications which may suffice to control and correct disturbances originating upon the standard diet. In other words, if the sighting shot is unsuccessful we must seek to determine the nature of the error, and how it can be corrected. No doubt these therapeutic diets are for the most part to be regarded only as temporary expedients. By their use freedom from symptoms and a gain in weight, in vigour, and in well-being can often be achieved. But the ultimate aim must be to restore the child as quickly as possible to the standard diet of health. Only when it has demonstrated its power to thrive on the standard diet can we claim to have achieved complete success.

It is on this subject of the therapeutic modification of the diet that I especially wish to invite discussion. In

order to open that discussion I choose three such modifications

- (A) High caloric feeding in post-infective dystrophy
- (B) Thickened feeding in the vomiting of refluxity, nervous vomiting, and hypertrophic pyloric stenosis
- (C) Feeding with a high percentage of casein in fermentative diarrhoea

[The speaker discussed the results attained by these devices, illustrating his remarks by charts.]

#### DISCUSSION

Dr. DINGWALL FORDYCE (Liverpool) first referred briefly to breast-feeding. The quality of maternal milk was, in his experience, seldom at fault, and the most powerful factor in modifying it was nervous unrest and instability. Chemical tests were of little practical value, but occasionally bacteriological examination was of the utmost importance. The demonstration of *B. coli* in the milk of apparently healthy mothers had explained the unsatisfactory progress of three of his cases. The relation of diet to general health and constitution was a complicated problem. The late Dr. John W. Simpson had been among the first to use thyroid extract in the treatment of wasting babies, and his results were very good. In order to influence the thyroid function, it was not, however, necessary to administer the extracts of the endocrine glands, adjustment of the diet, particularly by modifying the nature of the carbohydrate and the amount of fat, could effect the desired result. Success in infant feeding could not be attained by rule of thumb. Each infant must be regarded as a patient with a constitution demanding study. Practical infant feeding could be learned only in the clinical atmosphere of the bedside and the home. The time must inevitably come when the subject of the feeding of infants as part of the larger subject of the medical care of children would receive adequate recognition in universities and medical schools. When it did, this in itself would largely counterbalance many detrimental effects associated with propaganda in favour of proprietary foods and misunderstandings in child welfare. With increasing knowledge therapeutics in childhood was joining hands with prophylaxis. When the subject was suitably recognized it was very desirable that development should take the form of a department for the medical care of children, and not be limited to the relatively narrow subject of therapeutics in sickness.

Dr. G. B. FLEMING (Glasgow) thought that hardly enough attention had been paid to the quantitative modification of the diet in infancy. In his opinion underfeeding was an extremely common cause of malnutrition. He considered that the average infant less than 6 months old required about 55 calories per kilo of body weight for basal requirements, 5 calories for growth, 5 calories to make good loss in the excreta, and perhaps about 35 calories for muscular exertion—a total of 100 calories per kilo. It had to be borne in mind that marasmus, atrophy, or decomposition did not represent a disease but a state of malnutrition. He had been interested in the problem of whether this malnutrition was the result of a too rapid utilization of nourishment by the atrophic child. Rosenstein first suggested that infants should be fed according to their age rather than their weight. Investigations on metabolism had thrown considerable light on this problem. It had been shown that the basal metabolic rate of the overweight infant was no higher than that of the normal, and also that there was little difference in the milder degrees of malnutrition. When, however, the infant was about a third below the average weight for its age there was a fall in the metabolic rate, and this became progressive as malnutrition proceeded. His conclusion was a result of these investigations was that, when an infant's weight was 70 per cent of what it should be for the age, the requirement was 90 calories per kilo of expected weight instead of 100 calories. Beyond that point the caloric intake had to be further reduced proportionately to the fall in the basal metabolism and the diminution in

muscular activity. Roughly a reduction of one calorie per kilo of expected weight should be made for every 1 per cent the child is below 65 per cent of its expected weight. Thus at 55 per cent of expected weight the allowance should be 80 calories, and at 45 per cent 70 calories per kilo of expected weight. In trophic then, it appeared that there was no excessive utilization of food and that the condition was brought about by one or both of the other causes of malnutrition—starvation or malassimilation. These considerations were useful in helping to avoid gross errors of under- or over-feeding.

Dr LEWIS THATCHER (Liverpool) confined his remarks to the use of acidified milk. In many feeding cases the food that was being given was deficient not only in total calorie content, but also in protein value. The idea on for this was often not that the diet had not been recognized as deficient but that all attempts to give an adequate quantity had been attended by signs of intolerance. In many such cases he had found acidified milk most valuable. There was nothing new in the use of acidified milk to meet this difficulty. Buttermilk had long been used and Gmelin's artificial milk was a mixture of hut milk and extra curd. In practice, he thought that acidification was best brought about by adding an organic acid. He used lactic acid, as the method was not difficult and the degree of acidity was easy to control. 1 drachm of lactic acid (B.P.) was added to a pint of milk which had been boiled for two minutes and allowed to cool. It was important that the milk should be nearly cold and be constantly beaten with a spoon or shaken up in a large bottle till the acid was added slowly drop by drop. It was convenient to prepare the ration for the twenty-four hours at one time. The milk might be strained or whole and carbohydrate preferable in the form of dextrinulose added as considered necessary. It was better to give no more than five feeds if sufficient could be taken at each feed. This allowed of more complete emptying of the stomach and also of the administration of orange juice and water between feeds, a plan which was preferable to diluting the mixture. When the change over was taking place it was, however wise as in all modifications to build up the diet gradually. Mothers could prepare the milk quite efficiently after a demonstration from the ward sister. There had been two main explanations of the undoubted benefits obtained, the first was that the coagulated casein salt was in a finely divided flocculent form which passed easily into the duodenum, and the second that the essential process was one of debuffing. Marriott and others had shown that the buffer value of cow's milk was much higher than that of human milk which meant that about three times as much acid had to be added to it to change the reaction to an equal degree. The result was that in the process of digestion of cow's milk the hydrochloric acid in the gastric juice was used up for this purpose and little or none was left for keeping the stomach content at the optimum acidity for peptic digestion stimulating gastrointestinal motility and killing off micro-organisms. The formation of a finely divided curd ought also to facilitate fat digestion.

Dr L. G. PARSONS (Birmingham) agreed with the view that lactic acid milk was valuable in the treatment of certain types of case. He was in the habit of using milk modified by the growth of the *Streptococcus lactis* for his original culture he was indebted to Dr Alan Browne of Toronto. He thought that this form had certain advantages but the method of preparation was no so simple as that in which lactic acid was added. It was therefore less suited to out-patient and private practice. It was difficult to understand why sick and debilitated infants should thrive better on lactic acid than on other forms of acid milk. The fat and calcium absorption on lactic acid milk was not so good as on ordinary cow milk and the calcium absorption was considerably less than on hydrochloric acid milk. The probable explanation of its superiority was that it did not put so much strain on the acid base balance as hydrochloric acid milk. Svorog of Heidelberg had suggested that the value of lactic acid lay in the fact that it was synthesized to carbohydrate and stored as glycogen in the

liver. Lactic acid milk was useful in cases of pyloric stenosis when breast milk was not available. In that condition is a result of the loss of hydrochloric acid from vomiting, a state of alkalosis was liable to develop and led to convulsions and a fatal termination. The importance of giving an acid milk both before and after operation was therefore obvious. There was no objection to giving lactic acid milk to newly born or even premature babies. It could be given also over prolonged periods. One patient had taken it, owing to an oversight for twelve months on end with excellent results.

Dr C. W. VINING (Leeds) associated himself with those who regarded underfeeding as an important cause of marasmus, and pleaded for a more general use of calorie measurements of food. At the same time it was desirable to keep feeding methods as simple as possible. The chief merit of the calorie method was that it offered a means of regulating and controlling food requirements. There was room also for improvement in methods of measuring quantities of foodstuffs. The table spoon was commonly believed to hold half an ounce of fluid whereas its measure was nearer three-quarters of an ounce. Larger quantities than were intended were therefore administered when this domestic measure was used. He believed strongly in leaving young infants with their mothers even when the latter were poor and ignorant rather than in admitting them into a hospital ward where there was always the danger of stray infection. As a routine in out-patient hospital practice he employed mixtures of dried milk and dextrinulose. These were made up in three strengths and were dispensed at cost price. He had been impressed with the usefulness of lactic acid milk and had also had success with banana pulp feeding in the stationary type of case. He hoped that pediatrics would soon appear among the subjects of the final examination for medical students.

Dr CHERINE CHISHOLM (Manchester) strongly supported the speaker's contention that pediatrics did not occupy the place it should in the medical curriculum. She urged the use for teaching purposes of the abundant clinical material now to be found in special municipal wards for infants, infants hospital and well equipped Poor Law institutions. Such teaching could not be given in out-patient department. She was glad that Dr Cameron had emphasized the real value of proprietary foods as a temporary diet for prescription in cases in which some special need of digestion had to be met. She had found lactic acid milk prepared by culturing the lactic acid bacilli of great value in infants of the age of 3 months. In younger babies, he relied in bad cases on breast milk from foster mother. A supply of such milk should be available in every institution dealing seriously with infantile dystrophies. Her experience of the use of banana pulp had been disappointing. In several cases the immediate effect was good but after a week or two intolerance developed and the diet had to be changed.

Dr MARGUERITE IOWENFELD (London) said that a fundamental difficulty in the therapeutics of infant feeding was the lack of agreement as to the criterion to be chosen in arriving at a standard diet both in respect of composition and quantity. One school aimed at giving a food the composition of which approximated as closely as possible to that of breast milk, another took the actual energy needs of the baby as a basis. In the obstetrical department of the hospital she had taken part in a study of the amounts taken by normal babies at each feed during the twenty-four hours, together with a biochemical analysis of the milk. One point of considerable significance in the matter of the fat percentage had emerged. It had long been known that in both human beings and animals the fat content of the milk tended to rise towards the end of a feed. Experimental workers had found however that this was not invariable. This investigation had shown that two factors had to be taken into account. The first was the amount of fluid present. The greater the amount of fluid the smaller the percentage of fat. The fluidity of milk was greatest at the beginning or feeding. The second factor was the degree of direct pressure exerted on the areola. This was aided by using

degrees of pressure varying from that obtained by the gentle use of a breast pump to that resulting from vigorous digital expression. The greater the pressure the higher the percentage of fat. With a maximal amount of fluid in the milk and a minimal pressure on the areola, the content of fat might be 8 per cent below that obtained when the fluid was small in amount and the pressure vigorous. When, however, the pressure was maximal at the outset of a feed and minimal at the end, the percentages of fat could be equalized or even inverted. She was convinced, therefore, that no two infants would get the same percentage of fat from the same mother, even under identical conditions. It might be that the so-called overfed infant to which Dr. Cameron had referred was really the vigorously sucking infant, who obtained not necessarily in excessive quantity of milk, but a milk with a very high percentage of fat.

Dr. HENRY MACKAY (London) emphasized the point that it was not only necessary to have some knowledge of caloric values, but also to be able to instruct the mother as to the conversion of weights of given foodstuffs into the domestic measures available. She instructed the great variations that existed in this respect in different foodstuffs in common use.

## MESENTERIC LYMPHADENITIS AND ITS CLINICAL MANIFESTATIONS

WITH SPECIAL REFERENCE TO ITS DIFFERENTIAL DIAGNOSIS FROM APPENDICITIS

BY

G. D. F. McFADDEN, M.B., M.Ch., F.R.C.S.E.,  
ASSISTANT SURGEON TO THE ULSTER HOSPITAL FOR CHILDREN,  
BELFAST

MESENTERIC lymphadenitis was well known to physicians in the past under the name of the "strumous abdomen." During life it was guessed at on general symptoms, or from the *post-mortem* table an accurate scientific fact was recorded. It is only since abdominal section has become common that the protein aspects of the condition have been realized. Whether the glands are acutely or subacutely inflamed or have resisted their invaders, symptoms may arise at each step. An acutely inflamed appendix, a stone passing down the ureter, a carcinomatous obstruction, a duodenal or gastric ulcer, can be most accurately mimicked. In fact, there is hardly an abdominal condition for which laparotomy is commonly performed that may not be simulated by diseased mesenteric glands.

That these glands are frequently infected is common knowledge. The tubercle bacillus has been stated to be the causative organism. Still found enlarged mesenteric glands in 59 per cent of all *post-mortem* examinations in children. Dingwall Fowdree in fifty autopsies could trace tubercle bacilli in 20 per cent. McIndoe and MacConkey found 25 per cent of clinically non-tuberculous patients to harbor active tubercle bacilli in their mesenteric glands. No child is too young to be infected. De la Albera reported three cases on which he performed *post-mortem* examinations and found no lesion excepting caseating mesenteric glands. One child was 5 years of age, one 4 weeks, and one had been born only 7 days before. At the Ulster Children's Hospital twenty-five cases of acute appendicitis were treated during 1925 and 1926. So that if one considers the numbers that do not reach hospital these cases must be almost as common as cases of acute appendicitis.

Accurate diagnosis in the case of a patient who is suffering from a pathological condition of the mesenteric glands rests to a great extent on a knowledge of their physiological properties and of their anatomical distributions. The lymph channels follow closely the blood vessels of the same region. The glands are situated in relation to these blood vessels. There is as a rule three sets. The glands affected in mesenteric lymphadenitis are the ileo-cæcal, the mesenteric, the inferior mesenteric root gland, the middle glands in the transverse mesocolon, the

root glands at the origin of the superior mesenteric vessels, and the lateral aortic glands.

The flow of the lymph through these glands is as a rule direct from one to the proximal one. The lymph may jump from one set of glands to reach a more distant group. This occurs in intestinal infections where the juxta-intestinal group seems to be passed over and the middle mesenteric group infected. It occurs where the cæca drained has suffered a developmental change in position. The lymph may take a circuitous route to reach its termination if the glands in its direct route are destroyed by accident or disease. It is in this way that a diseased appendix may infect the subpyloric group of glands. Sometimes the lymph flows backwards, this occurs when its onward way is blocked. This has been cited as a frequent cause of phthisis, where the bacilli in the mediastinal glands have their efferent paths blocked and the backward flow of lymph carries the bacilli into the lungs. Radwin reports a case where a mesenteric lymph abscess was opened and drained. The surroundings appeared healthy. Four months later the cæcum and ileum were the seat of hypertrophic tubercle. This was in all probability a case of infection of the intestine from a backward flow of infected lymph.

Now pathological changes in these glands are a great worry to the surgeon when it comes to a question of diagnosis. In 6,000 to 7,000 cases admitted to various hospitals only 45 were correctly diagnosed. Even the time-honoured aphorism of appendicitis—pain starting at the umbilicus, followed by vomiting, followed by the pain settling down in the right iliac fossa—may attend the beginning of an attack of inflamed mesenteric glands.

At operation three main types of glandular conditions are found: (1) Discrete enlarged inflamed succulent glands. This type is found in children who have exhibited the symptoms of acute appendicitis. (2) A mass of glands grouped around a caecous gland or a small abscess. There is an acute inflammation of the whole mass, and often there is free fluid in the peritoneal cavity. These cases simulate acute appendicitis with abscess formation, occasionally they get intestinal obstruction. (3) The terminal or herled stage of lymphadenitis—a single gland or several caseified glands lying in the mesentery. It is this type that is usually found in adults. The symptoms simulate those of a duodenal ulcer, a renal calculus, or a chronic appendix.

It is noted that children suffering from mesenteric lymphadenitis have a long history of stomach trouble. This history may only be obtained after long and judicious questioning. The history of the complaint may date from babyhood, or from a distant severe illness, such as scarlet fever or measles. Other points to notice are the numbers of cases that suffer periodically from headaches, drowsiness, and loss of appetite for breakfast, these symptoms are probably the sequel of acidosis, a condition common among these patients. Unfortunately the urine of all children was not examined systematically in hospital, and it was after their acute attack—in some cases two years after—that my examination of the urine was made. In my series of cases acetone was present in 63 per cent. During an attack the percentage would certainly be higher. Nausea and vomiting are frequent in their history—some 71 per cent of cases. I am inclined to think that the acute abdomen due solely to acidosis of the older children does not exist, but that the real condition in these cases is an associated inflammation of mesenteric glands. Distaste for fats is a common symptom. Constipation is not more frequent amongst these cases than amongst the rest of hospital patients.

### Pain

The pain may be severe. A number of patients are awakened out of their sleep by the pain. One has drawn attention to the sudden onset and the sudden cessation of the pain. Although this is frequent, it is not so frequent as to be a good diagnostic point. The duration of the pain varies from five minutes to about two hours. It frequently starts at the umbilicus and settles in the right iliac region. It often starts in the right or left iliac region, sometimes in both. It may be epistemic, usually to the left side of the epigastrium, in certain cases,

to be mentioned later, the pain may have the sudden severity of a perforation, or be more chronic and simulate that of a duodenal or gastric ulcer.

When the cases in children that simulate acute appendicitis are considered it is well to remember that the conditions are equally common, at least in the province of Ulster. In England the group most commonly affected is the mediastinal group in Ulster the gland in the neck and in the abdomen are most commonly affected. In England the human type of bacillus is relatively more common than in this province, where the bovine bacillus is the commoner. The social status of the patients seems to have no bearing, the condition occurs so frequently in the well-to-do as in the poorer classes.

Most surgeons who have written on this subject have stated that it is a localized inflammation of the ileocaecal group. Undoubtedly it is the group most seriously affected, but thorough examination rarely fails to detect other glands enlarged, though maybe to a slight extent. The glands of the neck are nearly always palpable in the case. Lymphatic glands are more easily palpable in normal children than in adult, but in children with mesenteric lymphadenitis, hotty glands larger than in healthy children can usually be found. In quiet and subsiding cases the gland lying at the root of the inferior mesenteric artery can be palpated frequently is the gland in the right iliac fossa. Enlargement of the lateral sacral gland has often given me the clue to the correct diagnosis in a doubtful case.

The points of special significance in the history are the long period that symptoms have existed, the weak stomach or so-called bilious attack, periodically recurring pain dating from an original mild attack and becoming more frequent and more severe. (It is this peculiarity in the history that is the reason of the long duration of symptoms before the patient is seen by the surgeon.) The pain may begin at the umbilicus and settle in the right iliac fossa. The attacks of pain are usually preceded by headache and drowsiness. Vomiting is a frequent symptom before or after the pain and it does not as a rule affect the pain.

The common age for the patient to be seen by the surgeon is between 7 and 11 years; it is rare to meet a case under 3 years of age.

*Penal Symptoms*

Two cases had pain on passing water.  
One case had haematuria.

As regards physical examination the patient is often pale with bright red lips, the tongue is moist but often has a whitish fur. Acetone may be detected by the odour of the breath. The tongue of an acute appendix case is dry, redder. The pupils are more prominent and the mucous membranes to be brown in colour. A child suffering from mesenteric lymphadenitis has never a tongue of this type.

Hotty glands can be felt in the neck especially in the posterior triangle. The abdomen moves freely with respiration. There may be some muscle spasm in the right lower quadrant of the abdomen but no true involuntary rigidity except in those cases of Group 2 where there is much peritonitis and the glands are matted together. The muscles in the flank or the lower fibres of the external oblique are never rigid. Rectal examination will reveal nothing or an enlarged lateral sacral gland may be palpated. Nearly all authors state that there is tenderness at McBurney's point. Now a glance at the lie of the glands in the ileocaecal angle will convince you that this is an improbability. The maximum point of tenderness in acute appendicitis is most frequently McBurney's point in an appendix lateral to the caecum or lying retroperitoneally tenderness may best be elicited in the flank, above the crest of the ilium. Glandular affections never involve the oblique muscles here. In mesenteric lymphadenitis the site of maximum tenderness is not McBurney's point but higher up and more medial as might be expected the tender area extends upwards in a vertical manner under the right rectus muscle to the transpyloric plane (Fig. 1). This is the position of the inflamed mesenteric glands. I have never found this area of tenderness to betwix me, given other suggestive signs. Careful palpation of the left iliac fossa may show local tenderness or an enlarged lymphatic gland. Rectal examination is especially useful. If the finger is inserted to its fullest extent and starting in the middle line posteriorly is swept round the side wall of the pelvis an enlarged gland the lateral sacral or the gland of the promontory can frequently be felt. This lateral sacral gland is felt like a pea. Hyperaesthesia of the skin, simulating the hyperaesthesia or an acute appendicitis, is sometimes present.

FIG. 1.—Showing the area of tenderness in cases of lymphadenitis of the ileocaecal angle as compared with the position of McBurney's point. The area of tenderness may extend over the whole of the flared area or be limited to the area of 1. Umbilicus 2. Maximum point of tenderness in ileocaecal angle. 3. The ileocaecal angle. McBurney's point is anterior superior iliac spine.

The temperature varies. It is frequently elevated depending upon the type of glands found. In Group 2 it is frequently high it may reach 104° F.

Taking the above points into consideration the diagnosis of the condition can be made with confidence in practically every case.

*Group 2*

Here the glands have become caecous and are the seat of acute inflammation they are usually matted together with adherent intestines. There are more general disturbances. It is these cases that give the high temperature. High temperatures in these cases were also noted by Dingwall Fordyce. The mass may be adherent to the anterior abdominal wall giving rise to a true localized rigidity. The case has then the objective sign of an appendicitis. These cases are admittedly difficult to diagnose. If the condition is suspected then the expectant treatment is best. The treatment of the appendicitis and of the mass of glands will coincide if it is possible to keep the patient under observation. The position and type of the mass when the acute symptoms abate with the other clinical signs of lymphadenitis will decide the question. If the patient worries one it is best to operate. If a laparotomy is rarely harmful. A blood count is of no help in the diagnosis. There is usually a lymphocytosis of from 14,000 to 17,000 with 80 per cent polymorphonuclear leucocytes. The cases of inflamed glands may go on to abscess formation. The abscess may behave like an appendicitis abscess and burst into the peritoneal cavity bringing about an abdominal catastrophe.

*Group 3*

In this group the symptoms approach those of renal calculus, duodenal or gastric ulcer, or a chronic appendicitis. On looking over the records of the Royal Victoria Hospital for the last year I found some twenty cases which

[ THE BOSTON  
MAY 11, 1874 ]

Occasionally a mass of glands may simulate an abdominal tumour. The most common site for these masses simulating a growth is around the origin of the superior mesenteric artery. It may give rise to a chronic obstruction, and this together with a hard swelling and the wasting common to mesenteric lymphadenitis induces the clinician to decide that it is a case of malignant growth. Without a laparotomy the diagnosis is often difficult, and a microscopic section is sometimes necessary to decide the diagnosis.

Chronic intestinal obstruction is common enough. Four cases of occlusion of the rectum have been reported, and seven cases of obstruction of the common bile duct. Wilkely reported a case causing dysphagia and giving rise to a lump in the stomach. Hounth and Binning have reported cases of reute lens. Umbilical fistulae occur, and a cold abscess lying in the retroperitoneal tissues has simulated the psoas abscess of Pott's disease.

Before the satisfactory treatment of these cases is undertaken it is necessary to determine the symptoms and

Before the satisfactory treatment of these cases can be undertaken it is necessary to unravel the cause of the symptoms and the pathology of the condition. When the glands in the ileo-caecal angle and the main group affected, it at first suggests a diseased focus in the intestine of that structure, yet enlarged ileo-caecal glands in cases of acute appendicitis are an unknown occurrence. The appendix when removed in cases of enlarged mesenteric glands is admitted by almost all observers to be within the range of normal. It may show fibrosis or have a few surrounding adhesions—a state common enough in persons who go about free from discomfort. Cusson thought that 16 out of his 50 patients had some abnormality of the appendix. Appendicectomy does not cure all these patients, which would be the logical conclusion were it the cause. In a follow-up of 20 cases on whom appendicectomy was done in the Royal Victoria Hospital 12 were traced six to twelve months after operation, of these, 2 felt improved, and one patient who had had the appendix and the gland removed was cured. As has been stated previously, the time was really too short to determine whether a patient was cured, is periods of freedom of from one to two years are common enough.

On examining a series of sections

unable, by the mucosa

there

On examining a series of sections of these glands I was unable, by the microscopic appearance, to discover whether there was more peripheral or cortical destination. The latter would have indicated a lymphatic, the former a blood infection. The distribution of the diseased glands can best be explained by Crimmette's view. He considered that there is first an infection of the local glands, the infecting organism overcomes these glands and then reaches the blood stream. The lower end of the ileum is the site that favours the entrance of organisms. It is in this part that there is most stagnation of contents, and it is here that the retention of the intestinal contents clings from in acid to an alkaline medium. The glands in the ileo caecal angle are then the most likely to be picked out. When the infection has passed this barrier the whole lymphatic system becomes quickly infected.

It is difficult to decide definitely, as I have done due to the tubercle bacilli, whether the whole lymphatic system becomes quickly infected.

It is difficult to decide definitely if this infection is due to the tubercle bacillus or to another organism. The pathological changes in the lymph nodes are those most typical of tuberculous infection, namely, caseation or calcification, passing on to fibrosis or sclerosis. In the case of cold abscesses, suppuration is more typical, and this would not be the case if the infection was due to a pus-forming organism. Corner suggested that the seemingly normal lymphatic glands in the ileo-caecal region might be infected due to the infection of the lymphatic system.

direction was due to a pus-forming organism suggested that the seeming proneness of the glands in the ileo-caecal region to aento inflammation was due to the change at this point of the reaction of the intestinal contents from acid to alkaline. Tuberculous ulcers of the intestine occur most frequently in the lower part of the ileum. Strintheis considered the cases of acute inflammation of the glands to be due to the superimposition of secondary infection on a pre-existing old or healed tuberculous gland. A calf injected with human bacilli will show no effect, except that, some months later, the glands during the aera will be the seat of a chronic fibrosis or calcification. Might not these fibrosed and calcified glands found in the mesentery of man, with their infrequent generalization of tubercle, have a corollary in an infection with the bovine bacillus, which is the type usually found?

had calcified mesenteric glands. They had on for duodenal ulcer or chronic appendicitis seen how the pain may come on after food, or with nausea or vomiting. If the glands high up in the mesentery the pain is felt in the The skiagram usually shows good peristalsis of or some pylorospasm, with the duodenal cup badly hypermobility of the colon. The picture could be with that of duodenal ulcer, which is the diagnosis suggested. Pylorospasm due to lymphatic spleenleo-caecal angle has been demonstrated by B. Further resemblance to duodenal ulcer is imperio periods of freedom are not so characteristic, though may last for over a year. Exercise usually gives patients acute pain. Screening of the stomach denum by the "whitewash method" under the x-ray to show an ulcer. A good picture taken from a paired subject ought to show the glands, as they are in most cases. The test meal is within the limits of The two conditions may coexist. A diagnosis of appendicitis is rarely justified without a history of previous definite attack. Here again the acute attack be simulated by a previous attack of acute lymphatic Accumulate history taking ought, however, to help the diagnosis. The skiagram ought to reveal a shadow of calcified glands cannot be palpated. Owing to the site of tenderness, during a rapid examination, being put down as a McBurney's point these patients are often labelled "reflex dyspepsia" from chronic appendicitis. In all cases considered the appendix removed if it had not been previously dealt with. The more frequently state that there were adhesions on some fibrous of the appendix. The removal, however, of this organ cured 42 per cent of these cases. A good many of the patients were only treated for some six to twelve months and as a long period (from one to two years) of relief from symptoms is frequent in cases due to calcified glands, it is doubtful if the percentage of cures is ever as high as 42. Dissection of the urinary tract is often necessary in cases. In my series in children, metrorrhagia, one had bronchitis.

In my series in children, one patient had prun or meturation, one had hematuria. The prun is often brought on by exercise, it is stabbing in character and may radiate down, it may be felt in the right or left side Rest cures the prun Sir J Thomson-Wilker in 1922 had met with 42 cases of calcified mesenteric glands simulating renal disease Blood was present microscopically in 6 cases There was profuse intermittent hematuria over eight years in one case, this was cured by the removal of a calcified gland In 11 cases he operated and removed the glands, this operation cured the prun in these 11 cases Undoubtedly the diagnosis from renal disease may be very difficult The prun, its character and site, its association with hematuria, its provocation by exercise and relief by conservative oliguric prun If to these symptoms is glands in 59 per cent showing a shadow in the renal area in children Dingwall, the clinical picture of renal calculus three tubercle bacilli in 20 per cent of these cases there is no MacConkey found 25 per cent of tubercle bacilli in the prun cesses patients to harbor active tubercle bacilli in the prun cesses There Albrecht reported three cases on which 14 cases have been cystitis examinations and found no tangible evidence of metastatic mesenteric glands One child's plates taken at one 4 weeks, and one had been born only Pylorography and At the Ulster Children's Hospital twenty-five cases of appendicitis were treated during 1925 and

The 6 per cent of cases that ultimately develop signs of general tuberculosis could be accounted for by an infection with the human type of tubercle bacilli.

The common symptoms of acidosis may be explained by the interference with the supply of fats to the liver. The child's metabolism is easily disturbed. Frew showed that the urine of most children suffering from any acute disease contained acetone. The lower ileum and the appendix are great absorbers of fat; appendiceal coections are chiefly fat. A calcification and fibrosis of the glands of the ileo-caecal angle must to a great extent interfere with the supply of fat to the liver, and set up acidosis. It seems to me that this acidosis has some relation to the onset of the acute attack of pain in the right iliac region. A dietetic indiscretion, a period of nervous strain, or muscular exertion often starts an attack. Many organisms too latent till an acid is presented to them. In children first come the symptoms of acidosis, headache, drowsiness, and then pain.

The pain has been attributed to different causes by different observers. Corner thought it was due to the reflex action on the appendix. Carson attributed the pain to the irritation of the mesenteric nerves causing enterospasm. Thus, he thinks, explains the colicky nature of the pain, and its sudden onset and cessation. He actually saw an intussusception occurring when he was operating on a case of lymphadenitis. Probably Carson's explanation holds good in many cases. It would explain the colicky pain at the umbilicus at the beginning of an attack. The shifting of the pain to the right must be explained by the local inflammatory lesion.

It is easy to understand how a calcified gland in the mesentery with no recent inflammation can, on exercise, cause acute pain. The site of the pain will depend on the part of the mesentery affected. Its irritating presence will also give rise to pylorospasm or enterospasm by reflex nervous action, or its bony hard spicules may irritate a ureter and give rise to renal colic and haematuria. The movements of the intestine after eating will readily cause the calcified gland to act as an irritant, and bring about pain after food stimulating that due to digestive ulcer. The treatment, then, will resolve itself into preventing the condition by a clean milk supply, and in the established cases according to the type.

#### Group 1

In the succulent inflamed glands of children operation is not necessary and it is unsatisfactory. Fresh air, sunshine, dietetic treatment and alkalines are recommended. The diet should consist of large quantities of green vegetables and a liberal amount of protein. Excess of sugars cause fermentations and acid changes in the intestine and should be forbidden. Highly saturated fats are likely to be incompletely burned and to continue the acid state. I think small quantities of the unsaturated fat in Norwegian cod-liver oil are useful. It is probably absorbed higher up in the intestine than the diseased area. As a medicine small quantities of sodium bicarbonate after meals are useful in preventing the acidosis. When it has occurred large doses of the bicarbonate and glucose are indicated. I have never tried insulin. Fortunately the removal of the appendix does not harm the child if attention is paid to the acidosis.

When a gland abscess is present it may be treated by absolute rest in bed with only glucose and sodium bicarbonate by mouth and by rectum. It will usually subside. If the child appears to be getting worse under this treatment the abscess should be evacuated and wiped out with hipp, with as little disturbance as possible to the surroundings for the intestines are likely to separate leaving holes in their lumen. In cases where future obstruction seems to be pretty certain a side-to-side anastomosis from above the lesion to below it, will save many a life and hasten convalescence.

In cases of calcified glands I think the evidence is all in favour of their removal. Their close relation to the mesenteric blood vessels should be noted and the blood supply of the adjacent bowel not interfered with. In an account of the close relation of the gland to the blood vessels the surgeon thinks it dangerous to remove the

gland completely a partial removal of the gland will in many cases cause a cessation of symptoms.

Violet rays have proved to be of great use in the treatment of the disease in children and in the fibrosed glands of adults. Deep x-ray therapy is useful, especially in those cases of massed glands simulating tumours. The dosage should be light, as intensive treatment is apt to cause abscess formation.

#### Summary

- 1 Mesenteric lymphadenitis is of frequent occurrence in children. The most common period for the complaint is between 7 and 11 years of age.
- 2 Symptoms date back over a long period.
- 3 The history of frequent attacks of lassitude, drowsiness, headaches, and loss of appetite for weeks past is very common in these patients.
- 4 Attacks simulating acute appendicitis, duodenal ulcer, and other abdominal diseases are common.
- 5 Other enlarged glands will be detected.
- 6 The site of tenderness in inflammation of the ileo-caecal group of glands is not McBurney's point, but a situation higher up and more medial than this point.
- 7 Operation is unnecessary in the case of Group 1.
- 8 A calcareous gland causing symptoms should be removed.
- 9 The cause of the condition in children is probably infection by the bovine tubercle bacillus, with a superimposed condition such as acidosis causing an acute attack.
- 10 The acute abdomen of children due to acidosis is really caused by an underlying mesenteric lymphadenitis.

My best thanks are due to the surgical staffs of the Ulster Hospital for Children and the Royal Victoria Hospital for permission to make use of their case records to Dr. Vint or the Pathological Department, Queen's University for the supply of sections of the glands, and to the house-surgeons and out-patient sister at the Ulster Children's Hospital for their help in collecting the cases.

## THE TREATMENT OF CERTAIN MENTAL DISEASES BY RINGER-LOCKE SOLUTION

BY

JOHN P. STEEL, M.D. Ed.,

ST. LUKE'S MENTAL HOSPITAL, MIDDLESBROUGH.

Acting on the suggestion of Ishida, confirmed by Morowoka (*Journal of Mental Science* April 1927) a number of patients in the St. Luke's Mental Hospital, Middlesbrough, have been treated by the subcutaneous injection of massive doses of Ringer-Locke solution. The solution used contained, in a thousand parts, or distilled water sodium chloride 9.0, potassium chloride 0.42, calcium chloride 0.2, sodium bicarbonate 0.1 and glucose 0.1. The patients have been somewhat carefully selected and the debilitated general paralytic and the toxic case have been considered to be most suitable, but a number of the manic depressive type have received injections over a considerable period and latterly no sound or advantageous to treat the debility or senility in this way.

The aim in all the treatment has been to better the physical condition of the patient, but latterly in view of the results obtained we have felt that it is quite reasonable to expect a good deal of mental improvement in certain types of mental conditions. A dose of 1000 c.c.m. has been

injected twice a week, no trouble has been experienced in the introduction of the apparently large amount of fluid, and even the most debilitated patients, male or female, have shown no ill effects.

An ordinary two-way aspiration syringe of 100 ccm capacity is used, with a needle of suitable bore. If the bore is large there is considerable leakage from the site of the puncture, and if it is too small the back pressure on the syringe makes the giving of the injection a tedious process both for the patient and the giver. The syringe and needle are sterilized by boiling, where an antiseptic solution has been used for this purpose one has found difficulty in removing all trace of the antiseptic, and a slight local reaction has occurred. The flank or the back is the most suitable place, and each side is used alternately, the near side of the sciatic nerve should be avoided, and if the temporary swelling is at the level of the three spine a little more discomfort is caused to the patient.

The skin of the selected site is well washed with ether soap and then treated with iodine before being frozen with an ethyl chloride spray. It is impossible to give a general statement as to how deep the needle should go. In some cases the needle is passed definitely to the subcutaneous tissues, in others there is less discomfort if the injections are made into the superficial muscles. As a rule the treatment causes transient discomfort and nothing more.

The fluid has been injected at varying temperatures, but one has found that about 105° F is very suitable, and tends to cause less of a rigor than a temperature lower than that of the body. The fluid should be injected slowly, otherwise the tissues have insufficient time to avail themselves of their natural elasticity, and the patient becomes very restless and complains of a "drawing" pain. When the desired amount has been given the needle should be slowly withdrawn, and the site of the puncture massaged with iodine before being sealed with flexible collodion and covered with a swab. Slight oozing nearly always occurs if the injection has been actually subcutaneous, but this readily stops without interference. If the injection is made into the superficial layers of muscle there is, as a rule, no leakage.

The patient should be carefully propped up in bed by pillows so that the distended area does not take any pressure. Absorption is very rapid, and there is seldom any trace of the fluid after two hours. We have had none of the reported soddenness of the skin even after fifteen or twenty injections have been given.

If it is desirable to give intramuscular medication to the patient this can readily be combined with the Ringer-Loocke injection into the superficial muscles. The absorption of, say, kaesulphur has, it is thought, been much more rapid, and no after-effect has been observed.

About two to six hours after the injection most patients have some rise in temperature, attended in the majority of instances by a mild rigor. Morowoka states that general paralytics seldom have a rigor, but this has not been borne out here. Practically every patient of this type has a definite elevation of temperature after one or more of the injections, in one patient the temperature rose to above 102° F twice in the first twelve injections, in another 101.6° F was the highest figure recorded, whilst a third had a temperature of 103° F after the second and fourth injections, and no rise above 100° F subsequently.

The senile type of case, as a rule, shows little reaction of temperature, but in the toxic case there is a definite tendency to rigor. One such patient had a temperature of 103° F four times in the first fifteen injections, in another the temperature rose to 102° F after each treatment, whilst a third rose to 104° F after the first three injections and then settled down to an almost regular normal figure.

Usually the temperature subsides within twelve hours and suffering is unimpeded by any disturbance of the pulse or glands rests well. Sleep is usually much more tranquil, physiological but feels decidedly better.

The body has no contraindications. In only one case of the same patient by Ringer-Loocke solution been administered these blood vessels because a coexistent and spreading attack of the glands affected a matter of difficulty to find a suitable dose, the mesencephalic in the general paralytic was by no gland, the middle gland, indeed, we have found that in

the very rare cases where such existed they tended to heal more quickly when ordinary treatment was combined with the injection of Ringer-Loocke solution. Certainly, the tendency to secondary septic infection is much lessened.

Except for rise of temperature no complications have been observed. Morowoka states that in demented precox a rash is sometimes seen, this has not been the experience here with other classes of cases, only once has a slight rash been observed, and that in a patient of plethoric mind.

### Results

Treatment by the Ringer-Loocke solution has been carried on here with great regularity and comparatively extensively, but the results obtained with the treatment will not bear comparison with those of either Morowoka or Ishida in point of time, numbers, or actual benefit to the patient. Nevertheless very definite improvement has been observed which may be summarized as follows.

In toxic insanities, after the third or fourth injection it is quite usual to see a clearing of the complexion, and to find a returning power of free natural elimination, a return of tranquil sleep, with an accompanying mental improvement. In debilitated general paralytics, where the stage of auto restlessness has been reached, it has been noticed that after the third or fourth injection the patient becomes much more tranquil.

Daily catheterization was needed in one such case which was admitted in an extremely low condition. Enemata and hypnotics were a routine. After the third injection the catheter was used chiefly as a precaution, and after the sixth its use was discontinued altogether, after the seventh injection the daily enema was discontinued, as a dose of liquid paraffin was sufficient to ensure free elimination. Hypnotics are now practically never necessary, as the patient sleeps most of the night.

Another patient, having frequent and heavy seizures which resulted in a partial left-sided paresis, was treated by injection of Ringer-Loocke solution. Marked improvement was noticed in both the number and severity of the seizures after the second injection, and the paresis cleared up after the third. No further seizures have been noted. Restlessness is diminished, urine is being passed in full quantities, and a fair measure of sleep is being obtained.

Repeated treatment with Ringer-Loocke solution in debility of senility has been followed by really good results, restlessness diminished, elimination increased, there was less danger of the onset of stupor, and appetite tended to revert to the normal.

### Conclusions

Regular and repeated injections of the Ringer-Loocke solution have been of definite benefit in cases in which there was a toxic element, and the mental condition seemed to improve more rapidly under this treatment than when "forced" elimination alone was employed. In the debilitated toxic patient the time which must necessarily elapse before the toxic focus can be attacked is materially shortened.

The general paralytic in poor bodily health seems to benefit to a very considerable degree, in fact, the treatment is used here with a view to bringing the patient into a suitable condition for typhosomycin medication. In addition, with the bodily improvement there is an increase in the eliminatory powers. So far but little difference in habits has been observed.

In the "psychological" insanities little improvement has been noticed from the mental side, but even in this difficult class of patient the increased length of sleep and diminution of restlessness is of considerable advantage both to the patient and to the hospital.

I am indebted to the medical superintendent of this hospital, Dr H G Drake-Brockman, for his permission to publish details of the work.

## CONGENITAL WORD-BLINDNESS

BY

ALLISTER M MacGILLIVRAY, M B, Ch B,  
D O M S

SURGEON TO THE DUNDEE EYE INSTITUTION

In congenital word-blindness the visual memory for letters and words is defective, that is to say, great difficulty is experienced in learning to recognize printed letters and words, so that spelling and reading are exceedingly troublesome, or even impossible. No other defects may be found

in the eyes and eyelids, and no difficulty may be experienced with figures and sums. The condition is said to be uncommon, but it is highly probable that it is frequently overlooked. The following case is evidence of this.

A boy aged 14 years was brought to me by his widowed mother with the object of ascertaining whether his difficulty in learning the letters of the alphabet and his inability to read could be attributed to some visual defect. The family had only recently removed to Dundee from another district of Scotland.

The following history was obtained. He was sent to school at the age of 5 years. At once his teachers noticed that he experienced the greatest difficulty in learning the written letters of the alphabet and that he was totally unable to recognize written words, however simple. This peculiarity being attributed to lack of sense or stupidity he was related to and kept in the infant class throughout his school life even although he showed no difficulty in learning figures and in being able to do simple mental work.

On examination his vision was found to be 6/6 in each eye as confirmed by the figures on Snellen's type. The refraction was emmetropic. This boy was under 12 for his age, but healthy looking, bright and intelligent. He had had no serious illness and no history of eye troubles could be obtained in any other member of the family. When asked to read printed letters he only did so correctly after several unsuccessful attempts. He was unable to read even the simple word such as cat or dog, but the picture of a cat or a dog he once recognized and named correctly. Figures and easy sums such as are suitable for infant classes, presented no difficulty. He could write slowly and distinctly but was unable to do so to dictation. He showed a marked aptitude and keenness for drawing.

The patient was shown at a meeting of the Forthshire Medical Association in January 1927.

The chief interest in this case lies in the fact that its true nature was not realized until the boy had reached the age when he was about to leave school and try to earn a living for himself very heavily handicapped by his inability to read. Had the condition been discovered earlier special tuition in spelling and reading could have been instituted with the hope of overcoming to a certain extent this congenital disability. Several successful results have been recorded by various authorities.

The condition as has been said may very easily be overlooked the child's inability to learn his letters put down to mental backwardness or sheer stupidity. It is therefore highly important that all cases of children who exhibit a marked difficulty in learning their letters should be carefully investigated and special individual tuition adopted if congenital word-blindness be diagnosed.

## ANEURYSM OF THE LEFT INTERNAL CAROTID ARTERY SIMULATING PITUITARY TUMOUR

BY

S D LODGE FRCS G F WALKER MD MRCP

AND

M J STEWART MB FRCP,

LEEDS

THE patient a woman aged 52, consulted Dr S T Rowling on September 27th 1926 with a history of failure of left vision since January of that year. She noticed, as the first indication of disability that she was bumping into objects on her left side only. In July 1926 right vision began to fail but there were no other symptoms except slight dizziness of one month's duration. She was admitted to the General Infirmary at Leeds on November 1st 1926 complaining of headache and nausea in addition to the failure of vision. Examination revealed complete amaurosis of the left eye in the right eye fingers could be counted at two feet distance, but in the temporal field only. The pupils were dilated and sluggish the fundi were normal and showed no evidence of optic atrophy. The patient was drowsy and there was polyuria. It was thought that the hands and feet were slightly enlarged, but this was doubtful and the general appearances rather suggested hypopituitarism although without definite signs of myxoedema. It appeared that the condition was one of physiological block rather than of atrophy of the optic nerves and that decompressive operation might restore some degree of vision. The urine was normal as to constant weight and sugar tolerance and the blood sugar was within physiological limits. The Wassermann reaction was

negative. Further neurological investigation yielded negative results. A ray examination showed absorption of the posterior ethmoidal process, the sphenoidal air sinus being clear. A diagnosis of pituitary cyst was made.

At 4 p.m. on November 9th a cervical cataphorax took place. The patient complained of severe occipital pain and of flashes of light before the eyes. She vomited copiously, and gradually passed into coma. The pupils became contracted and sluggish and the arms flaccid. The abdominal reflexes were absent. The knee jerk was absent on the right side, just present on the left. There was a bilateral Babinski's response. The coma deepened, and death ensued at 7 p.m. Clinically it was suggested that the cataphorax was the result of haemorrhage into the tumour.

### Autopsy

At post-mortem examination on November 10th a firm, globular, pedunculated mass was found projecting upward from the base of the skull into the region of the pituitary fossa. On further investigation this was found to be an aneurysm springing from the left internal carotid artery the interior being filled partly with pale, laminated thrombus, partly with soft mixed thrombus, and partly with blood clot (see figure). The aneurysm was almost

Medial (antero-posterior) section through the central portion of the base of the skull showing the aneurysm situated on the top of the flattened out pituitary fossa and the optic chiasm. A Wall of an artery B pale firm laminated thrombus occupying a large part of its interior C off red blood clot D posterior ethmoidal process E pars posterior and F pars glandular of pituitary body G basi-sphenoidal air sinus occipital bone H sphenoidal sinus I left internal carotid artery

exactly spherical and measured 3.5 cm in diameter. It projected deeply into the base of the brain in the region of the interpeduncular space the under surfaces of the frontal lobes and the anterior extremity of the corpus callosum. There was much softening of adjacent brain tissue and the optic tracts and chiasma were stretched out ribbon like over the mass, obstructing its forward extension. Recent haemorrhage presumably from the aneurysm had taken place into the third ventricle and had extended from there both upwards into the lateral ventricles especially the right and downwards into the fourth. Escaping to the surface the blood had accumulated in the pia-arachnoid at the base of the brain and had even trickled down the spinal canal. The pressure of the aneurysm had also led to much flattening of the ellipsoidal with compression of the pituitary gland.

There were no other evidences of syphilis a scar near the apex of the left lung being regarded as tuberculous in origin. The gall bladder contained a solitary cholesterol gall stone.

### Histology

The wall of the aneurysm is composed of extremely dense fibrous tissue with much collagen and few and flattened cells and still bears some resemblance to the arterial wall from which it was derived. Some small foci of early calcification are seen in the inner layers. The contents of the aneurysm consist of typical rubeolous and thrombus in the one part and a mixture of blood clot and early thrombus in the other. There is no evidence of organization of thrombus. The pituitary gland, which is slightly compressed shows a considerable mass of colloid in the

paris intermedia The parotis glandularis is intensely congested, otherwise there is no evidence of pathological change

The case is of interest as exhibiting the presence of ocular symptoms in the absence of glandular or neighbourhood phenomena. Thus incongruity fortunately delayed operative measures, and so prevented what might otherwise have proved catastrophic surgical intervention

## FAMILIAL PELLAGRA IN IRELAND

BY

JAMES T. MCCARTHY, M.B., B.Ch.,

M.O.H., COOLRAIN DISPENSARY DISTRICT

THE fewness of the cases of pellagra reported from these countries in the past was due probably to the prevalent idea that the disease was confined to subtropical countries. Between 1850 and 1910 no cases appear to have been reported in the British Isles. The discovery of several unrecognized cases by Sambon and others in 1916 in England and Wales raised the probability that others escaped diagnosis. This and the fact that the disease must have become familiar to many civilian medical men serving in the great war combine to account for an increase in the number of cases since recorded. Even so the disease would appear to be of sufficient rarity here to deserve reporting. It is not unlikely that some cases still escape recognition, particularly cases of pellagra sine pellagra in countries of little sunshine. In this connexion, too, it may be pointed out that 1926 (in which year these cases were observed) and the previous year were years of exceptional sunshine in Ireland.

It appears probable that the first of the cases here recorded was an acute exacerbation of a chronic affection. Most Italian writers consider that the acute type is never primary, but always an exacerbation of the chronic. Wood and others, however, from their study of cases in the southern States of America, state that at least 50 per cent. are of the acute type. The view that the disease is due to an inability of the patient to use biologically valuable protein would appear to account for these two cases, in them such inability may have been a familial failing. The diet would appear to be a fairly useful one, it certainly is a very usual one in this country.

### CASE I

A woman who had been married fourteen months presented herself on May 27th, 1926. She complained of weakness and loss of energy. She was inclined to be sick in the mornings, and the menses had ceased. She was constipated, she wondered if she were pregnant.

She was of the melancholic type, and her mentality was sluggish, the pupils were very large. The face was grey and dark, giving the impression that it required washing. There was marked seborrhoea of the nose and mandibular region. There was a rash on the forearms extending about half way to the elbows, and on the backs of the hands to the metacarpophalangeal joints. On the thumbs it extended to the middle joint. It was much less extensive on the flexor surface of the forearms and did not come below the wrists. This rash she said, was of recent origin. The pulse was a little fast. The knee jerks were lively, and there was a suspicion of ankle clonus. No other physical abnormalities were found.

She was told that it was just possible that she was starting pregnancy, and asked to report later on. Her husband, however, was informed that no evidence of pregnancy could be found but that her general condition strongly suggested pellagra; this disease was, however, so rare that I hesitated before definitely diagnosing it.

She returned on June 14th. She was then very weak and had had diarrhoea for some days. She had intense vulvitis, moist and red. During the next few days the diarrhoea became severe and was only partially controlled by opium or morphine in one or other combination. There was distressing retching at this time, due probably to intense salivation, as food was not vomited.

On June 20th she presented all the textbook appearances of very acute pellagra. The rash on her arms and face had diminished somewhat and now resembled very closely the coloured plates of pellagra in Dr. Norman Walker's *Introduction to Dermatology*. She was very much mentally. There was still intense moist circumscribed dermatitis of the vulva. The anal region was red and excoriated, probably from the almost constant passing of liquid motions. There was vague tenderness over the spine, the abdomen was tender all over, but most markedly in the gastric region. The knee jerk could not be elicited on the left side, and only slightly and with difficulty on the right. She complained of pain in her back and lightning pains in the legs. The pulse was 120 and the rectal temperature 103°. Perhaps the most striking symptom was the intense stomatitis. The tongue was swollen,

clean to the point of "beefiness" (Sandwith's bird tongue), ulcerated deeply about its edges, and the buccal mucous membrane was ulcerated and fetid. The fuses could not be seen owing to the swollen tongue and soreness at the angles of the mouth. There were enlarged inguinal glands. Prostration was intense. She died of exhaustion on June 28th.

In support of the view that the disease was an acute exacerbation of a chronic condition, a few notes may be added. Inquiries locally reveal that her neighbours had considered her "not quite right," and had commented on this at the time of her marriage. Her husband informed me that a couple of months after marriage she became "gloomy" and developed "nigres" and unreasonable jealousies. She got out of her bedroom window one night and went to her mother's home scantily clad and barefoot. She had to be restrained physically at times from doing queer things, and there had been some talk of having her sent to an asylum. Her sister says she remembers her having to go to bed years ago because of "a rash about her neck." Her family history is given in connexion with Case II.

Her diet was that usual for people of her class in this country: bread-and-butter and an egg in the morning, potatoes, meat, and vegetable (usually cabbage) for dinner, and tea or cocoa at bedtime. This diet hardly suggests a deficiency disease.

### CASE II

A woman, aged 33, presented herself on July 28th, 1926. Her father had died of "heart disease," aged 56, her mother was alive, she had two brothers, of whom one was weak minded or erratic, and three sisters, of whom one was living, one had died of meningitis, aged 27, and the other was Case I.

She had been married two years and five months, and up to marriage had had good health except for dysmenorrhoea. About eighteen months ago she began to feel weak. She had a miscarriage in October, 1925, and saw a doctor afterwards. She has been weak ever since. The periods have been irregular since, recurring every two months, lasting about seven days, and varying in amount. She has to go to bed at these times. In the forenoon she feels dizzy and has noticed that her mouth fills with water. The bowels move every second day without medicine, and the appetite is fair. She says that her speech is affected and that she cannot continue speaking for long because her mouth feels stiff and tired. When going to sleep she has noticed that her mouth is inclined to fill with water, and she feels as if she could choke. She believes she has been losing weight for the past eighteen months. She presented dermatitis on the backs of the hands, and said that she gets this every summer and that her neck, too, gets very sunburnt. The rash covered the backs of both hands and arms forward on the extensor surface of the thumb to the middle joint, it was red, with a good deal of branny desquamation, and some scattered brown pigmented warty or psoriasisiform spots on an erythematous surface. There was one such spot on the neck. Her face was seborrhoeic, especially the nose and lower cheeks. The liver was rather easily palpable but not tender, the cervical glands were palpable. The pharynx was a little red. The pulse was 88, and the blood pressure 90/130. There was a suggestion of ankle clonus and both knee jerks were lively. All other examination gave negative findings.

She was advised to go to bed for a time and afterwards to avoid sunlight and to wear a veil. An iron and arsenic mixture was prescribed and instructions were given as to diet and general hygiene.

In February her sister reported that she was well.

The Registrar-General of the Free State has courteously informed me that two deaths from pellagra were registered in 1922 and 1923. They were of females aged 55 and 60 years.

## TRENDELENBURG'S OPERATION FOR REMOVAL OF A PULMONARY EMBOLUS

BY

NORMAN C. LAKE, M.D., M.S., D.Sc., F.R.C.S.,

SURGEON IN CHARGE OF OUT-PATIENTS, CHaring CROSS HOSPITAL,  
SURGEON, DOLINGBROOK HOSPITAL

THE operation for the removal of a pulmonary embolus, first suggested by Trendelenburg, is one that the surgeon can but rarely be called upon to perform. As a consequence the number of recorded cases in which an attempt has been made to remove the clot is very small, and the results almost uniformly disappointing. In the case here described an opportunity was afforded of testing the practicability of this rather dramatic procedure.

On August 5th 1926 a woman aged 19 was operated upon at Charing Cross Hospital for a chronic right-sided pain. A diagnosis had been extremely doubtful and an exploratory laparotomy was performed through a paramedian incision. The only

pathological structure discovered was a cyst the size of a large egg, at the right ovary. This was a nod very simply and without difficulty by ligation of its pedicle. The healthy appendix was also removed in the usual fashion. Convalescence was uneventful except for the presence of a very slight oedema of the right leg, which was attributed to a mild suppurative stasis. On August 10th, shortly after having left her bed for the first time, she gave a sudden cry of intense pain and collapse. She was immediately lifted into bed, where I saw her about a minute later. Her appearance was characteristic of a large pulmonary embolus. She was pale, with a mottled, patchy white and purple colour, the expression of extreme anxiety with eyes widely open and pupils dilated. Dyspnoea, a intense cough for every breath but was apparently unconscious. The diagnosis was obvious but it was very difficult to decide immediately whether recovery was possible. At the end of two minutes, however, he was still alive, which seemed to indicate that only one branch of the pulmonary artery was involved, operative intervention therefore was not only not imperative. Within the course of another two minutes, he appeared to improve considerably and regained partial consciousness. Violent paroxysmal movements of the whole body notwithstanding, connected with the air hunger dyspnoea still being intense and at the same time the bowel acted involuntarily. The movements could only be restrained by force and continued for a further two minutes, when suddenly he gave collapse and after one or two attempts, but ineffectively, at inspiration, apparently died. The heart nevertheless could still be felt beating feebly at the apex but at the conclusion was reached that a second clot had been detached which was now blocking the remaining branch of the pulmonary artery so that spontaneous recovery was impossible. After a moment's hesitation it was decided to attempt removal of the clot.

#### Operation

Within about a minute after a very happy cleaning of the hands and the perfunctory application of iodine to the chest wall with a scalpel and three pairs of artery clips as the only immediately available instrument, a semicircular incision was made at the level of the second and third costal cartilages. After turning up the flap of skin and fat the origin of a portion of the pectoralis major muscle was reflected outwards, the second intercostal muscle was detached from the cartilages and the latter then removed by rapidly cutting through them with the knife. This gave a limited exposure through which the margin of the pleura and the base of the pericardium could be seen. All pulsation on the heart had ceased but the operation was nevertheless continued. In hastily attempting to enlarge this aperture the pleura was torn and the left lung collapsed, better exposure of the pericardium was however thereby obtained. The pulmonary artery was still partially hidden by the border of the sternum and although an attempt was made to hook it forward with the finger and by artery forceps, heavily applied it quickly became obvious that the time of opening it and removing the clot would be almost impossible without further exposure. In the meantime a pair of bone forceps were available and a portion of the sternum corresponding to the length of the exposure and including about half its width was thus removed. The pericardium itself was now opened medially to the left phrenic nerve which could be seen coursing downwards over its surface and the artery was palpated in the hope that the clot might be felt perhaps broken up and driven through into the smaller branches. This failed, the clot could not be detected through the thickness of the vessel wall and nothing remained save extraction through an incision. Two artery clips were placed in close proximity upon the outer sheath and the index finger of the left hand was passed behind the transverse sinus to hook the pulmonary artery and aorta forwards. It was hoped that this manoeuvre would control the bleeding while at the same time rendering access easier.

An incision about an inch long was made longitudinally into the vessel on its anterior surface and immediately a large quantity of blood escaped ob-curing the field. By pulling the vessels forward with the finger the haemorrhage was to a great extent controlled but at the same time the pulmonary artery was so compressed that it became impossible to insert forceps or palpate the interior in order to determine the position of the clot. This method was therefore abandoned and a pair of soft bowel clamps placed across the roots of the pulmonary artery and aorta. Control of bleeding being now quite reasonable a finger was inserted into the lumen where the clot could be felt in the left branch of the artery with its base riding across the dividing ridge into the right branch which it partially obstructed. It was extracted with ordinary dissecting forceps and the wound in the vessel rapidly closed with a continuous catgut suture

keeping the edges well everted so that endothelium was in contact with endothelium everywhere. The aperture in the pericardium was also closed.

Direct massage of the heart resulted after an interval of a few minutes in a regular and reliable contraction. The effect of the heart was light but it was impossible to perform efficient artificial respiration to help the circulation owing to the large opening in the chest wall, positive pressure apparatus too was not immediately available. At this stage more than 1 c.c. of 1 in 1000 adrenaline was injected into the ventricle with remarkable effect, since the heart commenced to beat at a more regular and with increased force. This continued for a minute or so and great hope were entertained of recovery. Gradually however the encephalogram died away and the heart again became feeble and irregular. Massage was continued but although in intermittent contractions were obtained for several minutes, more no permanent effect resulted. The chest wall was closed and artificial respiration with further injection of adrenaline tried without avail.

The clot removed was about 2 inches long and tapered from the size of the finger at one end to two small branches about one-eighth of an inch each at the other. It showed in addition several side branches and from it I hope it was brought probable at the time that it came from the internal iliac vein.

#### 1. Thrombotic Embolization

The postural wound was well healed in its whole extent without any sign of infection. The abdominal cavity was clear and the ear of the appendicectomy clearly marked without adhesion.

The right broad ligament was slightly thicker than the left and around the ligature on the ovarian pedicle was a small blood clot but there was no indication of surrounding thrombosis. The internal iliac vein was carefully explored throughout its length no sign of a clot or of roughness at the endothelium associated with the recent detachment of a clot were seen. The left internal iliac the external and common iliac superficial and deep femoral indeed all the larger veins of the body were examined but no signs of thrombosis could be found. The left lung was collapsed but otherwise healthy in the lower lobe of the right was a rounded area of a bright cherry red colour possibly a recent infarction. In the right auricular appendage of the heart a small irregular and apparently antero-posterior clot was found.

The difficulties confronting the surgeon in this operation are those of circumstance even more than those of technique while the decision to perform it is not an easy one to make in view of his limited experience as to whether

spontaneous recovery can occur and the knowledge that no permanently successful case has been recorded occurs as a hesitation born of despair. In his original article Trendelenburg says that two conditions must be fulfilled:

- (1) Can the diagnosis be made with sufficient accuracy?
- (2) Is there sufficient time for an operation? He answers both of these questions in the affirmative and states that there is an average interval of fifteen minutes between the onset of the symptom and death. He also shows partly as a result of experimental investigation and partly from actual experience of the operation in two cases that the pulmonary artery may be compressed for forty-five seconds without fear and that this may be repeated if necessary after the re-establishment of the circulation for a short period of time.

Experience of the present case would appear to suggest yet another query. Is it possible to resuscitate a patient after removal of the clot when the heart has already ceased to beat? The remarkable effect of the injection of adrenaline directly into the heart and even more the great stimulant effect upon the auricle or forced intermittent aeration of the lung rendered possible by modern appliances—for example in tracheal catheter and lung-motor—probably make resuscitation feasible even in such desperate cases. In future he two methods should be used from the moment the clot is removed, the time taken by the preliminary stages of the operation makes it possible for the necessary apparatus to be available when required, at least in institutional practice.

Sketch showing the manner in which the pulmonary artery and aorta are exposed. The flap of the chest with its clearly marked lateral branch is indicated by 'a'.

When the belated decision to operate has been made, further delay is occasioned by the fact that nothing is ready, instruments usually have to be obtained from a distance, and the surgeon is taken unawares, and so has no stereotyped technique to follow. To add to these difficulties the patient's posture as he lies in bed is by no means an ideal one for this type of operation, the only possible approach through the chest wall cannot be carried out rapidly in the absence of adequate instruments, while the lighting is apt to be very poor.

Although definitely recommended by Trendelenburg, the opening of the pleura was quite inadvertent, since it was thought that the pleural reflection might be brushed well out of the way by gauze dissection. The experience of this case, however, shows that valuable time would thus be lost, and that there need be no hesitation in deliberately opening the pleura. This is especially so since in all cases some variety of positive pressure apparatus should be brought into use before the operation is completed. It must again be emphasized that the efficient and early application of such a method is probably the most important single factor in re-establishing the circulation. In experimental work *in vivo*, with perfused hearts which had been maintained in a quiescent condition in the cold chamber, I found that the most effective stimulus to restarting the beat was the stretching of the musculature of the auricles by the entry of the perfusing fluid under pressure, *in vivo* a similar effect was obtained by positive intermittent ventilation of the lungs.

The fact that no adequate source of origin of the clot was found in this case is, in a way, not to be wondered at, since in many cases of fatal pulmonary embolism, both post-operative and spontaneous, it appears to be impossible at the post-mortem examination to trace the vessel from which the clot rose. The shape of the clot in this instance showed that it had not originated in the auricular appendix, but probably in the internal iliac vein, along which it had grown without producing sufficient changes in the surrounding endothelium to be visible. It was then carried into the circulation as a whole, and not, as is frequently pictured to be the case, a small fragment detached from it as it grew from the internal into the common iliac vein.

The small bead of pus surrounding the ligature was

likely enough aseptic and due to the chemical irritation of the antiseptic in the catgut (picric acid), but this was not put to the proof.

One further point of interest is the fact that the leg had been lightly massaged twice a day after the operation as a prophylactic against femoral thrombosis, according to the suggestion of Moisson. This is of doubtful value even in the case of the femoral vein, and can obviously be of no avail in the commoner cases of pelvic thrombosis. Until our knowledge of the etiological factors which determine the onset of thrombosis is much more extensive than it is at present no rational method of prevention can be suggested. It would seem possible that the role of sepsis has been exaggerated in the past, for the incidence of embolism in frankly septic cases is smaller than in those performed with all aseptic precautions. It is at the same time true that in the majority of cases of embolism the temperature chart shows a slight rise for a few days following the operation, but whether this is due to some mild grade infection (perhaps by an ultra-microscopic organism since the ordinary pyogenic organisms are rarely recoverable at post-mortem examination) or is a true traumatic pyrexia remains to be proved.

## THE TREATMENT OF SOME OCULAR DISEASES WITH ULTRA-VIOLET LIGHT

BY

E. R. CHAMBERS, AND F. J. A. MAYES,  
 F.R.C.S.D., M.R.C.S., L.R.C.P.  
 OPHTHALMIC SURGEON, IN CHARGE OF THE LIGHT DEPARTMENT,  
 BRISTOL ROYAL INFIRMARY

SINCE the introduction of the ultra-violet light apparatus at the Bristol Royal Infirmary we have endeavoured to arrive at some conclusion as to its effect on some of the ocular diseases subjected to this treatment. Hitherto we have been working on rather "blunderbuss" methods, as very considerable work has yet to be done in sorting out the rays most helpful in medical treatment, the rays range from the near ultra-violet through a big spectral field up to the far ultra-violet, differing considerably in their action, the short being strongly irritative and destructive, whereas the long are more penetrating and stimulative. Still, even with the present methods ultra-violet light plays a very important part in clearing up a number of ocular conditions which, in the past, have been difficult to deal with.

We have made no local applications of light to the eye, but have used the mercury vapour lamp for general irradiation of the skin, the first exposure is of three minutes' duration, this is increased by two minutes at each subsequent treatment up to twenty minutes, two exposures a day being given. The distance of the patient from the lamp is 36 inches. Care must be taken that the eyes are not exposed to the light. The knobby coloured goggles

only slightly and the Conjunctiva and Lids—These have all been in her back and of a type which has resisted symptom was the m

ordinary treatment. In chronic and long-standing blepharitis conjunctivitis it has been our practice to have tonsils and adenoids dealt with, and an autogenous vaccine prepared from the lids when possible, it is in cases which have continued in spite of this treatment that we have found ultra-violet light valuable. The curative effect of light seems to be due to the improvement in the child's general condition, thus increasing its resistance to infection. The treatment is also very beneficial in cases of chronic and recurring sties.

**Phlyctenular disease of the Cornea or Conjunctiva**—Undersized, delicate children, often with enlarged cervical lymphatic glands, respond most readily to treatment. The throat should always be examined for tonsils and adenoids, and these conditions dealt with before the light treatment is begun. Here again astonishing results are often seen in the child's general condition. As a result of light treatment the cure of phlyctens appears to be more permanent than before this method was used, recurrences being much less frequent.

**Corneal Ulcers**—The chronic and recurring corneal ulcer so often met with in children, associated with conjunctivitis and blepharitis, does remarkably well under the action of ultra-violet light treatment.

**Tuberculosis of the Conjunctiva**—The best result that we have had so far occurred in this disease.

A child aged 10 was seen with a large tuberculous ulcer, situated in the outer part of the upper lid. Surrounding the ulcer were tuberculous nodules whilst the remaining conjunctiva was thick and velvety. There was a chain of lymphatic glands in the neck, the upper ones soft and evidently on the point of breaking down. The patient was seen by a surgical colleague who advised removal of the glands but before doing this it was proposed to use ultra-violet light. In order to estimate the value of

this particular method no local treatment was applied to the ulcer the eye merely being kept clean with simple antiseptic lotions. After a month's treatment the glands had become very much smaller and those that were breaking down were hard. The conjunctival ulcer was cleaner and smaller until the remainder of the conjunctiva showed obvious improvement.

Light treatment was continued and in four months no trace remained of either the ulcer or the lymphatic involvement. The child's general condition had improved out of all recognition.

This is the only case of tuberculous conjunctivitis that has been subjected to light treatment, but the result is extraordinary when it is remembered how very unattractive treatment has usually been in these cases.

**Tuberculous Keratitis**—In a case which was probably tuberculous of the cornea, occurring in a child aged 10, in which there were present a small central corneal ulcer, with grey infiltrations in the substance of the cornea, iritis, and enlarged cervical glands, the tonsils and adenoids were first dealt with, and subsequently ultra-violet light was used as an adjunct to local treatment. The progress was slow, but there was a gradual and very marked improvement in the child's general condition, which we had not been able to obtain by any of the usual methods of treatment. The enlarged cervical glands have disappeared and except for some corneal scarring the eye has cleared up and remains quiet.

**Injury to the Eye**—Ultra-violet light appears to be useful for cases in which the eye remains intractable after an injury, particularly if the cornea has been involved.

In our patient a young adult who had lost one eye in childhood and received a severe injury in the other by an explosion of a detonator ultra-violet light was tried after all local treatment had failed to allay a mild iritis and vascular condition of the cornea. In spite of treatment the patient's general condition had been below par after the accident. He responded splendidly to ultra-violet light the eye became quiet and the improvement in his general health marked. The use of light seemed to give this patient just that improvement in his general condition which we had not been able to attain with other methods.

There is no doubt that ultra-violet light is of considerable value in dealing with many ocular conditions seen in children. The progress of the eye depends very largely on the condition of the child's general health and it is in this direction that we have found ultra-violet light very helpful. Used in suitable doses it will certainly give good results where other methods have failed, but patience is needed by the operator and patient nothing being gained by trying to speed up recovery by big doses. Nor is it a 'cut-and-run' in diseases of the eye; further work will no doubt very soon show us the type of case in which we may or may not expect good results.

## GAS GANGRENE FOLLOWING A MOTOR ACCIDENT

BY

F. W. MARSHALL, M.B., B.S. DORCH.  
LITCHFIELD STATION

Cases of gas gangrene are comparatively rarely met with in civilian surgical practice and the following case is therefore thought worthy of record.

A strong healthy youth aged 19 employed as a gardener was admitted to the Litchfield Cottage Hospital on July 23rd 1927 with a laceration having been kneed on his bicycle by a motor car.

On examination there was a transverse laceration about two inches long of the left shin in its lower third, it exposed a portion of the tibia, antiseptic wash was lavaged. There was also a piece of skin about the size of the palm of the hand missing from the outer aspect of the left ankle and the extensor tendons were thus exposed. Both wounds were irrigated with road dirt.

After a general anaesthetic a scrubbing brush and were then washed with spirit. The wound edges and all obvious dead tissue were excised and a glove drain was inserted into the shin wound. An antiseptic serum 1500 units was given.

At 10 a.m. on July 24th the temperature was 101°F and the wounds were very painful. Although their outward appearance was much better before swabs were taken from the shin wound for bacteriological examination and the leg was dressed again. At 7 p.m. on the same day the temperature had risen to 102°F and the inner side of the leg was swollen and brown. Short of a surgical emphysema the leg was noted just above the internal malleolus. Under general anaesthetic a long incision was made on the inner aspect of the leg, dividing the skin and subcutaneous and a Carrel tube was inserted and Dakin's solution was subsequently injected every two hours.

On the morning of July 25th the patient was somewhat better.

The wound however looked unhealthy and the bacteriological report was that the swabs yielded a profuse growth of *B. welchii* and *B. proteolyticae*. At 7 p.m. his condition was much worse. The temperature was 101°F. He was looking very toxic and both the inner and outer aspects of the leg were swollen and aetere tender. There was a peculiar sour odour from the wound.

The patient was therefore anaesthetized and the wound previously made was extended. The muscle was brick red and very friable and on squeezing bubble of gas could be expelled. All infected muscle was therefore excised. A similar knee to ankle incision was made on the outer side of the leg down to the middle of a portion of which was excised. The wound was swabbed with hydrogen peroxide and Carrel's tubes inserted. 30 ccm of anti-gas gangrene serum were given intramuscularly.

On the following day he was much better. 60 ccm of anti-gas gangrene serum were given.

On July 26th he was still improving and a third dose of 30 ccm of serum was given. The wounds were still very offensive and were covered by greasy black slough. They were being swabbed with hydrogen peroxide twice daily and Dakin's solution was being injected through the tube every two days.

On July 30th he was still doing well and a second dose of antitoxic serum was given. Bacteriological examinations showed *B. welchii* and *B. proteolyticae* to be still present.

On August 5th both wounds were comparatively clean and granulating and a bacteriological examination on August 8th showed a profuse growth of *B. proteolyticae* but none of *B. welchii*. The wounds were being swabbed daily with hydrogen peroxide and dressed with gauze soaked in Dakin's solution. The Carrel's tubes were removed as they were becoming embedded in granulation tissue.

On August 31st both wounds were covered with Thiersch skin graft obtained from the thigh. They subsequently did very well and on September 22nd as they were almost healed the patient was allowed to get up.

The serum used in this case was supplied by Messrs. Burroughs Wellcome and Co. and I am informed by Dr R. A. O'Brien of the Wellcome Research Laboratories that it contained a large amount of *P. welchii* antitoxin and probably a small amount of *B. tetani* antitoxin but it was not the polyvalent antitoxin against *B. welchii*, *Librium plique*, and *B. oedematis* which was used during the war.

The literature on this subject previous to the war period is somewhat scanty. Simonds in 1915 collected 175 cases from the literature, 111 of which were classified as follows: Compound fractures 61, lacerated wounds 20, operation wounds 11, gunshot wounds 10, and hypodermic needle punctures 9. It will be seen that in this series compound fractures and lacerated wounds form at least 45 per cent of the cases.

The most authoritative contribution to the subject covering the period of the war appears to have been made by Weinberg and Seguin who produced the condition experimentally in the guinea pig and definitely established the anaerobic group of organisms of which *B. welchii*, *B. oedematis*, and *Librium plique* are the chief—as its cause. They advocated serotherapy in the treatment of the condition but insisted that radical surgical measures must also be taken and all diseased tissue thoroughly excised.

In civilian practice Christopher reported nine cases from the literature covering the period 1915-22. They were all traumatic in origin. Baldwin and Cilmour collected 64 cases by twenty-six authors during the period 1922-27. Of these 20 were traumatic in origin, 20 complicated obstetrical and gynaecological cases and the remaining 18 belonged to that class in which the causative organism had been derived from the patient's own intestinal canal. The authors also record two personal cases each due to *T. tetani* and each treated energetically by antitoxic gangrene serum and by appropriate surgical procedures. In each case the end result appears to have been excellent.

Bricker and Welch report three fatal cases from 1910-1911 in which *T. tetani* was isolated and in the third *T. tetani* was identified. In each case a tetanizing organism (Welch bacillus) serum was given in large doses and radical surgical procedures resorted to.

It would seem then that our best hope in dealing with this condition depends on three main factors: (1) Early diagnosis, (2) early treatment, (3) it is necessary to adopt the operation of ephelage as described during the war—that is to say the excision of all contaminated tissue regardless of its amount or situation caused. (3) The condition appears to some extent can follow by the early and energetic use of antitoxic serum. This serum may be

either of the polyident variety, or it may be a specific putrescine for the particular causative organism, the latter having first been determined by bacteriological examination. In conclusion my thanks are due to Dr J. J. Menton, Director of the Staffordshire County Bacteriological Laboratory, for his kindness in performing the many bacteriological examinations necessary during the course of this case, and for many useful suggestions as to its treatment.

## GAS GANGRENE FOLLOWING A MOTOR ACCIDENT

EDWARD C. ELLIS, M.B., Ch.B., D.P.H. Ed.,  
 COCKERMOUTH

As the opportunity seldom arises in civil practice for observing gas gangrene, the following case is, I think, worthy of record, occurring as it did after a motor accident, cases of which are now so frequent both in town and country districts.

A youth aged 18 ran into the rear of a motor car sustaining a punctured wound of the left leg produced by the projecting arm of the luggage carrier on the car. The head of the fibula was torn away from its articulation and the rim of the car passed through the interosseous space tearing the tibia, anterior to the extensor digitorum longus, and the posterior tibial vein, to the apex of the fibula was cracked just below the head. The posterior tibial artery was intact.

On admission to the cottage hospital the wound was enlarged thoroughly cleansed with hydrogen peroxide, and binned skin and tissue removed. The posterior tibial vein was ligatured at its commencement and the muscle and sheaths repaired. The wound was closed anteriorly drainage being provided through the wound in the calf of the leg. A prophylactic injection of antitetanic serum (1500 units) was given locally. The limb was cold but in a few hours became warm and comfortable. Within eighteen hours of the accident a foul acid smell from the leg was noticed and the toes were cold. Twenty-two hours from the time of the accident the whole limb from just below the knee was cold discoloured and swollen. The patient was delirious with a high temperature and a rapid feeble pulse. After consultation amputation was decided upon and carried out forthwith just below the knee. On cutting the stitches the underlying tissue was seen to be discoloured and of putty-like consistency. On cutting from portions of the vein distal to the ligature gas also escaped left open and irrigated by the Carrel-Dakin method. The patient had a relapse about a week after the amputation accompanied by a rise of temperature and delirium, the cause of which is described below. Eventually he made a good recovery.

I am deeply indebted to Dr J. T. Selby, Cockermouth, and Mr. Richardson Keswick, by whose courtesy I am able to publish these notes.

### Bacteriological Examination

A small piece of vein and tissue which showed the presence of gas was sent for examination, and the report stated that two types of Gram-negative bacilli were present in large numbers, the one short and plump the other much larger and exhibiting, in many cases terminal or subterminal spore formation. Gram-positive cocci were also present in small numbers chiefly in chains resembling streptococci. The following facultative organisms were isolated from the vein and tissue: *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Staphylococcus saprophyticus*, *Streptococcus faecalis*, and *B. welchii*. A large Gram-positive, pleomorphic, capsule-forming bacillus (*B. welchii*) was isolated also. No spore or non-motile bacillus (*B. welchii*) was isolated also. No spore or microbe and actively streptococcal. No *B. tetani* were recovered. There is no doubt that the emphysematous condition of the wound was due to the activity of the *B. welchii* in the tissues. but additional interest was given to the case because a slough taken from the wound was given to the case because a slough patient had a relapse with rise of temperature etc. showed on culture a mixture of the presence of a motile spore-bearing bacillus which produced red and gas in carbohydrate but failed to coagulate milk and did not liquefy gelatin. It was therefore not a typical organism of the *B. welchii* group but resembled the clostridium *B. multiseptatus*. It was not pathogenic to summer pigs but produced in them a large amount of oedema.

The question now is to where the contraindications had arisen. The road surface had been recently tarred and was comparatively clean but the patient was wearing his firm trousers part of which had been driven into the wound. Examination of blood stained and non-blood stained portions of the trousers showed the presence of *B. welchii*, *B. coli*, *Streptococcus faecalis*, *Staphylococcus aureus*, and *B. megaterium*, no microbes other than *B. welchii* were recovered.

This case is of interest from several points of view. One is the exceedingly rapid onset of gangrene and the presence of terminal and subterminal spore-forming organisms, emphasizing the need for prompt prophylactic inoculation of antitetanic serum in all street accidents, although no typical *B. tetani* were isolated, the inoculation may have inhibited their growth. Secondly, we have the presence of two gas-forming bacilli, the typical *B. welchii* being evident in the region of the wound, while *B. multiseptatus* was demonstrated in a slough removed a week later.

Furthermore, it points to the advisability of treating all punctured and contused wounds occurring in street accidents and in agricultural districts by open irrigation and dressings, although a somewhat similar case recently treated by primary suture of muscle and sheath resulted in complete functional recovery without sepsis or complications. My patient, with thirty-three years' experience in an agricultural district, tells me that he has never had a case of gas gangrene, but his husband has four cases of tetanus. Of these four cases three were punctured wounds, one was an abrasion of the elbow received in a cycle accident, in this case the wound was covered over with adhesive plaster by the patient himself. In this district a large number of wounds received by farm labourers and road workers in the course of their work come under my eye, and it is only in punctured and contused wounds that any complications have to be feared. Simple incised wounds lend themselves to easy cleansing.

The minus of infection was here provided by the clothing, and the primum for growth by the injured yet viable muscle, assisted by stasis of the circulation and lowering of the temperature of the limb due to shock.

## Memoranda: MEDICAL, SURGICAL, OBSTETRICAL.

### DIABETES MELLITUS TREATED WITH GLUKHORMENT

At the request of the Medical Research Council the clinical effect of a preparation called "glukhorment," introduced by Professor van Noorden in May, 1927, for the treatment of diabetes, has been investigated. It was stated to be obtained by strong trypsin digestion of fresh pancreas substance, and to contain no synthetin or related gummino compound. This statement, however, has been shown to be incorrect in the recent article by Drs. Dale and Dudley (JOURNAL, December 3rd, p. 1027).

In two cases of diabetes the effect of glukhorment has been observed on sugar and ketone excretion, on the blood sugar concentration, and on the general clinical condition. From tablets a day were given after meals. In both cases definite reduction of the glycosuria and the blood sugar was obtained without any appreciable effect on the ketosis, weight, or general clinical condition. Similarity in the action of glukhorment to synthetin was at once noticed, in regard to the slow onset of action, its prolonged action after omission, and the production of toxic symptoms of vomiting and depression.

**CASE I**  
 A man aged 57, a moderately severe diabetic requiring 10 insulin was fed beyond his carbohydrate tolerance until a glycosuria of some 30 grams was produced (diet carbohydrate 140 grams, protein 45 grams fat 150 grams). Glukhorment reduced his blood sugar concentration slightly and his sugar excretion from 20 to 15 to 10 gram. No nausea or depression was produced.

**CASE II**  
 A girl aged 11 with very severe diabetes. The dose of insulin was reduced sufficiently to allow glycosuria of about 25 grams. She was receiving 20 units of insulin twice a day and 100 grams carbohydrate 60 grams protein 60 grams, and fat 100 grams throughout the test and for ten days previous. She had been entirely stable and her carbohydrate tolerance still high. Glukhorment a day produced vomiting, loss of appetite, and days and her sugar excretion fell from 25 to 1 or 2 gram. The number of tablets was reduced to three for two days, after which she again tolerated food without nausea or vomiting, the glycosuria remained low, and the blood sugar was reduced. On continuing

the gliukhoimint the sugar excretion rose to nearly its previous figure. This was again induced by further administration of the tablets but this time she was able to tolerate only three without gastric disturbance. Synthalin 20 mg was then substituted for the gliukhoimint as this was judged to be the equivalent amount from information received from Dr Dudley but it caused severe nausea, headache, and depression and 10 mg of synthalin appeared to be about the clinical equivalent of three tablets of gliukhoimint. When synthalin was omitted the glycosuria and hyperglycaemia returned though to a less degree than before.

In this case the toxic symptoms of nausea, vomiting, headache and depression caused by gliukhoimint and synthalin were precisely similar. The difference on commencing and the continued action on omitting gliukhoimint (in both about two days) is exactly what happens in cases where synthalin has any effect. Slight proteinuria without casts was produced by gliukhoimint, but no haematuria, jaundice or mobilization was observed.

From the above results it might appear (roughly) that three tablets (0.9 gram) of gliukhoimint contained the equivalent of 10 mg of synthalin and that it therefore has about 1 per cent of the clinical activity of pure synthalin. The chemical analysis of gliukhoimint, however, suggests a higher percentage of synthalin or a synthalin-like substance so that the potency of the active principle of gliukhoimint is probably reduced either by its poor absorption when mixed with dried pancreatic extract or by the antagonistic action of the latter.

In conclusion, the clinical results observed with gliukhoimint in the cases of diabetes are practically the same as may be obtained in many cases with synthalin—namely moderate reduction of glycosuria and hyperglycaemia and the production of similar toxic symptoms.

### A CASE OF PROTRACTED LABOUR

The following case of protracted labour, apparently due to premature ossification of the foetal skull, seems worthy of record.

Mr. X gives a maternal history as follows. Her first child was born at term the labour being so quick that she was unable to have attention and the child died during birth. The second child was born two years later the confinement being normal; the child is alive and is now 10 years old. No further pregnancy occurred until the one under consideration.

She started to be in labour five days after the expected date and continued in labour over two days without sending for me. I found the abdomen rather larger than usual; the presentation was a left occipito-anterior and on vaginal examination I was unable to feel the promontory, although the head was rather higher than usual, the os was dilated to the size of a half-crown piece, and the membranes projected.

I saw her again early the next morning and found that no progress had been made and indeed even after noon the conditions locally were just as at my first examination, but her pulse rate had advanced to 120 and her tongue had become dry. I then had her removed into hospital and performed a Caesarean section. The child weighed 10 lb 6 oz and mother and child were quite well.

On examining the child's head I found that the anterior fontanelle was smaller than usual and I then arranged for an x-ray examination of the head and also for a conrol examination of the head of another child three weeks older. The negatives show that the frontal, occipital and parietal bones give a much more dense shadow in the child in my case two days after birth than the one of the other child three weeks older.

I wonder if such a condition of the foetal head could have been diagnosed before birth and if not, how often some general practitioner has been blamed for an unfortunate result which he could not have been expected to anticipate, however scrupulous he might have been in his ante-natal care.

Oldham

FRANK RADCLIFFE, M.D., J.P.

### ACUTE PERITONITIS COMBINED WITH LABOUR

The following case is worth recording as illustrating the difficulty of recognizing acute abdominal conditions during and after labour.

A married woman aged 39 was admitted to the maternity ward at Saltburn Infirmary on September 15th at 11 a.m. Two years earlier she had a child weighing 7 lb (instrumental delivery) and three years before that he had been in a surgical ward with a very intracapsular cystitis due to *B. coli*. I saw her at 7.30 a.m. when her temperature was 100.8° pulse 104 respirations 23. She said she had been feeling unwell for about a week with abdominal pain which she ascribed to tight lacing in order

to conceal her condition. She had done her ordinary work and had not mentioned her pain to her friends. She complained of abdominal pain but not more than many women do in labour. She also said her abdomen was tender but he did not report palpation. The abdomen gave the impression of rather excessive liquor amni and the position of the foetus could not be made out. The os was about the size of a half-crown and the head was not engaged. The position of the head could not be diagnosed with certainty. The pains had become weak and she was given one sixth of a grain of morphine. She was examined again about three hours later. She still complained of some abdominal pain and tenderness; the pulse and temperature were about the same. The os was then found to be about the size of half a crown; the head was still above the brim and was in the right occipito-posterior position. The pain was stronger and the general condition quite good. The head was easily flexed and rotated into the right occipito-anterior position when it engaged at 6 p.m. An enema was returned unchanged. The membranes ruptured three-quarters of an hour later and a female child weighing 6 lb was born normally twenty minutes afterwards. The placenta came naturally, five minutes after the child.

That evening the temperature was 98° pulse 135 respiration 40. She was comfortable except for some slight abdominal pain. Next morning the temperature was 98° pulse 132 respirations 40. She had vomited several times in the night and she was slightly distended and tender. No physical signs could be found in the chest.

A large enema was given and a faecal motion obtained but no flatus. In the evening the temperature was 100.6° pulse 135 respirations 60. Vomiting had continued and distension was marked and there was free fluid in the abdomen. A needle was inserted and turbid fluid was withdrawn which was not blood stained and had no smell.

My surgical colleague, Dr Kempe, opened the abdomen and found general peritonitis but in spite of careful search no local lesion to account for it. He expressed the opinion that it was a case of pneumococcal peritonitis. The abdomen was drained and closed.

Her condition went from bad to worse and she died thirty-six hours later.

The fluid withdrawn from the abdomen gave a copious growth of pneumococcus. The child appeared to be perfectly healthy.

JOHN ARMITAGE, M.P.C.S., L.R.C.P.  
Medical Officer, Maternity Department, Saltburn Infirmary.

### TRIGEMINAL NEURALGIA PRECEDING ACUTE GLAUCOMA

The following is a brief account of an unexpected sequel to an apparently straightforward case of trigeminal neuralgia or tic douloureux.

A woman aged 65 had been subject to neuralgic headaches all her life; they had become more severe and localized during the last two or three months. They occurred at frequent intervals, usually began on waking and consisted of a dull right-sided headache (hemispherical) with brief stabbing dart or pain in the right temple, forehead and cheek, radiating over the right side of the scalp. At such times the whole of the affected area was exquisitely tender. Sight was not affected and the attacks were usually relieved in a few hours by rest and aspirin.

Examination on September 10th, 1926, showed nothing abnormal in the heart, lungs, alimentary or nervous system. The blood pressure was 110/60 mm. Hg. The fundi were normal. A diagnosis of trigeminal neuralgia for which no exciting cause could be found was made. The patient was anxious to proceed on a tour to the Continent but was dissuaded from this by her medical adviser who suggested a short period of rest and observation. On September 25th, 1927, she awoke with excruciating pain in the right forehead and cheek coming on in paroxysms of a few minutes' duration. The parts were tender to touch and the eyes were closed. A little circumcorneal injection was noted on the right side. Vomiting followed but without relief; the pain being eventually relieved by 1/4 grain of morphine. The patient passed a good night but the next day the pain was still present and was localized in the right orbit. The tension of the globe on that side was increased and there was much circumcorneal injection but no disturbance of the acuity of field of vision. In the evening the diagnosis of acute glaucoma was no longer in doubt, the cornea being tense, tension — and the measures and on the condition failed to react to palliative measures and on September 29th Mr. Hugh Jones of Liverpool performed the operation of trephining and iridectomy on the right eye. Recovery was uneventful. During the past year there have been occasional mild headaches but the severe neuralgia attacks have completely ceased.

The manner in which glaucoma in the prodromal stage may mimic other disorders is well known and this case is of interest in presenting a picture of itching tenderness to headache and of trigeminal neuralgia for some months without any symptoms until the actual onset of acute glaucoma.

My thanks are due to Dr R. B. Edwards of Mold from whom the patient was referred for help in the preparation of the notes.

R. SYDNEY ALLON, M.D., M.P.C.P.

Pu-blic Castle North Wales.

## Reports of Societies.

### INCIDENCE OF THE MINOR PSYCHOSES

At a meeting of the Section of Psychiatry, held at the Royal Society of Medicine on December 13th, Dr MILLAIS CURRY read a paper entitled "A study of the incidence of the minor psychoses—then clinical and industrial importance." The President of the Section, Dr R LONDON-Down, was in the chair.

Dr CULPIN explained that the work, of which this paper was a summary, arose from an inquiry into telegraphists' cramp, which was undertaken by the Industrial Fatigue Research Board. Cramp was assumed to be a fatigue phenomenon until the investigators discovered that the symptoms appeared to point to a psychological rather than a physiological basis. Dr Culpin was then given the opportunity of interviewing cramp subjects and of comparing them with a control group of persons not so afflicted in order to discover whether cramp was definitely associated with other symptoms of a recognizably psychoneurotic type. This was found generally to be the case, the other symptoms being often of a degree which would lead to the diagnosis of a severe psychoneurotic state. It also became evident that there existed an unexpected prevalence of these symptoms among the control group of presumably healthy people. Students in the school of telegraphy contained 19 per cent of subjects having symptoms of significant severity. The results of this particular inquiry were published by the Stationery Office under the title of "A study of telegraphists' cramp." The question then presented itself: Was the fact that minor psychoses were associated with cramp attributable to some feature of the work, or was it a phenomenon common to the general population? Thus the investigation was next directed towards ascertaining the proportion of the general population which suffered from the minor psychoses. Associated with this question were two others—Did the distribution of such subjects vary in different occupations? and, What was the probable influence of occupation in determining the incidence of psychoneurotic illness? Sickness records were obtained from various Government departments and from private firms. It became clear that disabilities arising from the minor psychoses played a great part in swelling the totals of time lost through illness. Many employees of various trades and professions were interviewed. The subjects were given a short psychological examination on a more or less formulated plan which elicited the replies necessary to form a diagnosis. Dr Culpin gave several examples of the types of replies received. Observations were made on day-dreaming at work, the effect of noise, and the reaction of ex-service men towards their war experiences. These phenomena were found to vary according to the temperament of the subject. In addition to the psychological examination, Miss May Smith tested the subjects independently by the McDougall-Schuster dotting machine, the "pursuit meter," and the piezograph, an instrument which registers the pressure exercised in using the Morse key. The results of these tests showed some correlation with those of the examinations. It was found that the dotting test was the best objective procedure to be associated with the results of the psychological examination. An interesting point in connexion with this test was that obsessional subjects produced extremely good dotting records surpassing those of normal people. Examples were given of the responses of subjects suffering from hysteria, hysteria with anxiety, pure anxiety, and obsessional states. The standards of assessment were then discussed by Dr Culpin. The subjects were put into six groups assessed according to absence of symptoms or to the degree of symptoms. Roughly 50 per cent of the total number examined were found to be free from symptoms. Sickness rates varied, but they appeared to be independent of the number of minor psychoses that were found in each group. Laundry workers had as high a percentage of high assessments as clerical workers, but illness rates were low. Satisfaction of the workers with their work seemed to be an important factor in illness. It was found that there was no significant statistical differ-

ence between the results of the two sexes. Dr Culpin's general conclusions were as follows: the dotting test kept a check upon the results of psychological examination; there was a high proportion of persons in the general population suffering in varying degrees from the minor psychoses. There was no reason to believe that there was any active selection of particular occupations by psychoneurotic people, except in the case of art students, where the results of investigation confirmed popular belief about the "artistic temperament." The results suggested that the commonly supposed "causes" of psychoneurotic illness were merely factors in exacerbating a previously existing condition. But the fact that such illness was absent in some groups indicated the importance of studying exacerbating factors that must be present in those groups with a high sick rate.

In the course of a brief discussion the President remarked that such an investigation opened up many interesting and important questions from the clinical and industrial standpoints. Sick rates had been shown to be affected, probably accident rates might be affected, and the whole question of the efficiency of the work might depend on whether the employer or employee were suffering from the minor psychoses.

### SUPERNUMERARY BREAST

At a meeting of the Section of Pathology of the Royal Academy of Medicine in Ireland on November 11th the President, Professor T T O'FARRELL, showed a specimen of supernumerary breast, which had been removed by Mr Doolin.

A married woman, aged 45, the mother of twelve children, had had a nipple-like swelling in the right groin for twenty years. Two years ago it began to increase in size, but there had never been any discharge or sign of a duct opening on the surface. At the time of operation (tumour in the left groin) showed subcutaneous. Owing to its nipple-like appearance and the fact that it was situated in the nipple line, the possibility of a supernumerary breast was considered. The tumour, with a surrounding ring of skin and subcutaneous tissue, was removed under local anaesthesia. It was about the size of a walnut, and appeared to consist of two parts, a deeply situated portion closely resembling a scirrhous carcinoma, and a superficial rather spongy tissue, the interstices of which were filled with a yellowish, crumbly material. It consisted chiefly of irregular glandular acini lined by columnar epithelium cells containing many mitoses. In places the acini were round but in others very tortuous, suggesting adenocarcinoma. Some of the spaces contained concentrically arranged cells suggestive of cell nests. Groups of acini were widely separated by masses of necrotic tissue, which contained fat crystals. There were patches of large clear cells containing fat globules closely resembling the cells of sebaceous glands. They did not form definite glands, but nevertheless appeared to be included in, rather than to be part of, the growth.

Mr W Doolin said that on removal milky material had exuded, and on pathological examination the growth had proved to be a supernumerary breast. Cell nests had been present, and in the literature he had only found two references to cell nests, which had occurred in cases of ordinary carcinoma of the breast.

Dr W D O'KEEFE did not think it possible for a pathologist to say what the origin of the tumour in this case had been. He had seen cases of ordinary carcinoma of the breast in which cell nests had been present, and, in fact, thought it was rather extraordinary that cell nests were not found often.

### Ophthalmic Cases

Dr ALAN MOONEY showed three specimens of gloma retinae, and a microscopic specimen of cylindroma of the lacrimal gland. Two of the sections exhibited were gloma endophytum, and the third a gloma exophytum with involvement of the optic nerve. The first specimen was particularly interesting because it was the second eye involved, it was in a very early stage, and it originated in the ganglion cell layer of the retina. Parsons had only reported 5 out of 54 cases as being of that variety. The first eye was removed when the patient was 12 months old, and he believed it contained a large growth. The second eye was enucleated four months later. Macroscopically the eye presented three chief foci, the largest being the size of half a small pea, besides these there were

many tiny satellites scattered over the surface of the retina, which was not detached. On microscopic examination the largest focus was made up of the usual type of cells found in gliomata. At the most posterior part of the focus were present many of the so-called "rosettes" which were found in much greater numbers in the earlier stages of a glioma. The area of the growth was "rosettes" were present was more vascular than elsewhere, and the blood vessels had very thin walls. The optic nerve was normal and there had been no recurrence. The second specimen was a glioma growing from the inner layers of the retina, which was in place and the optic nerve was normal. In the case of the glioma exophthalmos the growth arose from the outer nuclear layer causing detachment of the retina. It pushed the crystalline lens forward till it was practically lying against the ball of the cornea then by causing secondary glaucoma. The tumour showed many dead white granules due to calcareous degeneration; this condition was only found in gliomata which had existed for some time. This patient was 2 years old and two days after the enucleation on the child had a severe haemorrhage, presumably due to the optic nerve extension ulcerating into the central artery of the retina. Some weeks later the socket contained a nodule about half the size of the enucleated eye which was probably a recurrence of the growth. Since then the child had been undergoing a course of x-ray treatment the whitish nodule was still present in the orbit and about the same size. The child had enjoyed good health since the operation so that the spread of the growth into the brain had probably been arrested. The other eye was normal. The last specimen he showed was a cylindroma of the lacrimal gland. Tumours originating in this gland were relatively rare and of the 132 cases which Parsons had collected only one was a cylindroma though 48 other varieties of lacrimal gland tumour were described. The specimen exhibited was composed of cylinders of hyaline connective tissue between which ran a network of tumour cells there was a complete row of cells surrounding each cylinder. In places the cells were grouped round a central lumen which in a few cases contained red blood cells. Broken up blood cells were found extravasated in some parts of the section and in these places were to be seen masses of amber-coloured pigment, probably of haematogenous origin.

Dr EUPHRA MAXWELL, referring to the case of cylindroma of the lacrimal gland said that the patient was a woman aged 40 who had first felt pain in the left eye in 1917. In 1922 the eye had become displaced forwards and slightly downwards and a soft palpable tumour was found in the lacrimal cornea. X-ray treatment was then given and there had been no change in the size of the eye for four years. In 1926 there was an increased enlargement of the eye and more pronounced displacement. The patient complained of pain and double vision in certain directions. Two applications of radium were followed by shrinkage in the size of the growth, and the vision returned to almost normal. In July, 1927 the tumour again began to increase in size and vision was almost lost. A corneal ulcer and glaucoma were found. It was decided to remove the eye since this operation the patient had had two treatments of radium and was better, but Dr Maxwell thought that it was too soon to predict the outcome. These tumours were rare, and Dr Maxwell believed that there was a certain amount of malignancy present in them. She had only seen four cases in which, on microscopic examination, a tumour of the lacrimal gland had been found.

#### Insulin and Lactic Acid Metabolism

Dr J. J. McGRATH in a paper on the influence of insulin on the metabolism of lactic acid described research in the *Städtischen Krankenhaus* in Mannheim Germany under the direction of Dr F. J. LEBER and announced conclusions from the results obtained. An endeavour was made to discover if insulin had any influence in the Meyerhof process. White mice used in the experiments were killed by sudden total immersion in carbon dioxide snow which prevented any post-mortem variation in the lactic acid content. The lactic acid, sugar and glycogen in the whole body of the animals were estimated. The first

series of seven experiments consisted in the intraperitoneal injection of insulin, and the determination of the amounts of lactic acid, glycogen and sugar present thirty minutes later. The amount of lactic acid present was not changed by the injection of insulin. In a second series it was shown that the amount of insulin injected caused the blood sugar to fall 50 per cent, and, further, that more than 50 per cent of the sugar which disappeared from the body after the injection of insulin must have been tissue sugar. Also, by reference to B. SINGER and LEBER'S figures, it was deduced that the burning of the amount of sugar which disappeared would not change the respiratory quotient by an appreciable amount. In the next four series of four experiments each rat was given lactic acid alone and with insulin was injected intraperitoneally and it was found that the injection of lactic acid caused no change in the carbohydrate content of the body though some of the acid had disappeared in thirty minutes. The injection of insulin did not alter the lactic acid values, and the loss of carbohydrate due to the injection of insulin was similar to that in the first series of experiments. The next series of experiments indicated that only 60 per cent of the lactic acid injected was absorbed from the peritoneal cavity and of this absorbed amount 50 per cent had disappeared after thirty minutes had elapsed. In the last series of two experiments dextrorotatory lactic acid was injected thus being the form found in the body. It was thought that it might give results different from those obtained with the racemic form. It was found, however, that although more of the dextrorotatory lactic acid was irrecoverable after a lapse of thirty minutes, this rate of disappearance was not influenced by insulin. It was also shown that the amount of sugar lost was not altered by the injection of lactic acid. In this series the injection of dextrorotatory lactic acid seemed to cause a slight increase in the glycogen present in the body, this increase was not in the liver. It was concluded that neither the lactic acid pre-existent in the body nor the injected lactic acid, was affected by the injection of insulin.

Professor J. M. O'CONNOR thought that Dr McGrath had made a definite advance in the study of the physiology of insulin. If the results were treated statistically a further advance might be made.

Dr A. R. J. DUNN thought that perhaps the time allowed for the action of insulin (thirty minutes) was short. In the dog as well as in the human being he personally had found that it took at least two hours before any effect began to be demonstrable on the blood sugar. As there was no certainty that insulin was absorbed very rapidly and as nothing was known about the manner in which insulin acted it was not possible to state definitely how long the interval would be before it began to act with the lactic acid.

#### GYNAECOLOGICAL SYMPTOMS DUE TO PANCREATIC CYST

At a meeting of the Section of Obstetrics or the Royal Academy of Medicine in Ireland on December 2nd Dr BERNARD SOLOMONS (Master of the Rotunda Hospital) in the chair, Dr D. J. CONNOR read a report of a case of pancreatic cyst which had given rise to gynaecological symptoms. The clinical details were as follows:

The patient had a history of amenorrhoea for three months with profuse vaginal discharge and a feeling that her abdomen was getting bigger. Her face was bronzed with the sun and she had a rather healthy look. The enlarged abdomen gave the impression of ascites rather than of a dense tumour and there was unmistakable evidence of fluid in the abdomen. The uterus was normal in size and shape and position but an indurated mass was felt in the pelvis. A profuse discharge was seen flowing from the cervix but it appeared certain that the absence of signs of inflammation made it quite certain that the case was one of non-infective leucorrhoea. The lungs were normal. From the physical findings it was surmised that the case was one of tuberculous peritonitis complicated by tuberculous tubes though the appearance of the patient was rather against this diagnosis. She was continued at the end of a fortnight but the symptoms were unchanged except that the abdomen became larger. There was no shifting dullness and the tumour was much better defined. The mass in the pelvis proved to be a loaded sigmoid and when the abdomen was opened a large cystic tumour of the pancreas retroperitoneal in position and below the transverse colon was seen. It was opened and drained. A tube was inserted and kept

in position by a purse string suture. The abdomen was closed in layers, and dressings of sterilized vaseline were applied, to prevent blistering of the skin from the irritating discharge, at the end of four weeks the fistula had completely closed, the leucorrhoea had disappeared, and menses had returned.

Dr Cannon said that these growths were essentially retention cysts, and not proliferating ones like cystadenomas of the ovary. Their removal was therefore not necessary in order to effect a radical cure. Should the cyst, however, be so small that it would be impossible to anchor it to the abdominal wall, enucleation would be the ideal treatment. To drain a cyst under these circumstances involved great risk of general peritonitis from the irritating fluid. He concluded that pancreatic cysts were rare tumours which were very difficult to diagnose, and might be easily mistaken for other pathological conditions. When the abdomen was opened they were easily recognized by their anatomical position, which was retroperitoneal and either above or below the transverse colon. If the tumour was large there was no need for enucleation, since conservative treatment would effect a radical cure, but if the tumour was small such treatment might cause general peritonitis. The pathological report of the specimen was that the fluid showed a tendency to clot such, but no action on egg albumen after two days. The sediment consisted of blood and pus. On cultivation *B. coli* was isolated. These findings indicated infective changes, perhaps, in a cystic condition.

Dr D G MADILL drew attention to the difficulty of relating the presence of the pancreatic cyst with the general gynaecological symptoms of the patient. Dr F S BOURNE thought that in cases of this kind some symptoms of pancreatic obstruction were to be expected, which would appear in the faeces. Dr BETHEL SOLOMONS dwelt on the difficulty in diagnosis in this case, and mentioned that other non-gynaecological tumours with pelvic symptoms were hypopharyngeal, displaced kidney in the pelvis, the spleen, and mesenteric tumours.

Dr CANNON, replying, said he thought that gynaecologists would probably meet with these cases as frequently as surgeons, and should be equally able to treat them. He referred to a somewhat similar case which he had seen, in this there had been shifting dullness. At operation a large retroperitoneal tumour had been found. He thought that this case might have been mistaken for a case of ascites. If a small pancreatic cyst was found it would be difficult to know whether to leave it until it grew larger and then to remove it, or to excise it at the time of operation. He personally would leave it. He thought that these cases were not really so difficult as they appeared from textbooks to be. He had recently removed a mesenteric tumour in a child, aged 2, much more easily than he had expected. It was possible that some cases might be functional. The faeces in his first described case were normal in colour, but had not been microscopically examined. There had been no symptoms of diabetes, and no sugar in the urine.

#### Ovarian Teratoma

Professor A H DAVIDSON read notes on a case of teratoma, and showed a specimen and slides. He said that solid teratomatous tumours of the ovary were rare and usually malignant, but teratomatous cysts of the ovary, or dermoids, formed about 10 per cent of ovarian tumours. In these were commonly found ectodermal structures such as skin, hair, teeth, nails, and sebaceous glands, endodermal structures such as thyroid tissue and mucosa of small intestine and air passages were rarely present. These teratomatous cysts were usually innocent, and only became malignant in about 3 per cent of cases. The interest in his case lay in the fact that it exhibited thyroid tissue alone, and in the last ten years there had been no more than four similar cases reported.

The patient was 39 years old, had been married twenty years, and had had three children, the last pregnancy being ten years before the present date. She complained of pain in the back and right side, headaches, and slight vomiting. Her menses occurred regularly every twenty-eight days, they lasted for nine or ten days and the loss was considerable. There was no leucorrhoea, the appetite was good and the general health satisfactory. The vulva and vagina were normal, the cervix healthy, but the uterus was enlarged to the size of a large pear by an interstitial myoma. The left ovary was very multicystic. The right was

enlarged to the size of a goose egg and was seen old in consistency, it was adherent to the peritoneum in the region of the superior and right lateral aspect of the bladder and of the right anterior fossa of the abdomen. There was some difficulty in separating the tumour, and various bleeding points had to be tied. Right salpingectomy, left salpingo-oophorectomy and total hysterectomy were also performed. Convalescence was uneventful and there had been no sign of any recurrent trouble up to the present time. The pathological report of the case was that there was a solid encapsulated tumour in intimate contact with the ovary. The cut surface presented a somewhat peculiar appearance with scattered areas of haemorrhage, it was surrounded by a dense capsule which merged into the ovarian tissue at its upper pole. Microscopically the tumour was composed of thyroid tissue with alveoli of varying size, some of which were lined by low and others by high epithelium, many of them were filled with a colloid material, while in others there was only an indication of the lumen. The capsule was composed of fibrous tissue and contained no ovarian structures. It was an ovarian teratoma and there was no evidence of malignancy in the sections, but cases had been reported of such tumours appearing histologically benign and later giving rise to metastases.

Dr D J CANNON believed that in a typical solid teratoma, if it was malignant, all three embryonic layers were represented. In this specimen only one layer was represented, and therefore he doubted if it was malignant and was inclined to consider it benign. Dr SOLOMONS said that the teratoids which he had met with were much larger than this specimen. He believed that the best classification of teratoids was into malignant and benign, for either could be present.

Professor DAVIDSON, replying, said that a dermoid was a tumour which developed in an ovarian cyst. It seemed to him quite feasible for a growth of thyroid tissue to develop in the ovary, and grow to such an extent as to make it solid. Solid teratomata were all essentially malignant.

#### Improved Gynaecological Instruments

Dr BETHEL SOLOMONS showed Bonney's myonectomy forceps, which he had improved by putting rubber at the ends of the blades, thus, he said, prevented damage to the vessels. He had found two new uses for the instrument: (1) when splitting the uterus in his operation for sterility, (2) it was an efficient clamp to prevent soiling of the vagina in performing a total hysterectomy with enucleation of the body, or when there was any suspicion of septic material in the uterus.

He showed also a modification of De Lee's stethoscope, which he had found most useful. The part which was applied to the abdomen was movable, making it easy of application to the pregnant abdomen. He used De Lee's stethoscope in conjunction with Rubin's apparatus when working single handed, it was easy with the stethoscope to hear the oxygen passing through the tubes, and to confirm the result given by the manometer.

Professor A H DAVIDSON said that Bonney's clamp was a very useful instrument, and the new use for it to prevent soiling of the tissues by clamping off the cervix seemed to him very practicable. Such soiling was always a difficulty in performing a hysterectomy. Dr D G MADILL said that he had not used a Bonney's clamp until about six weeks ago, when he had used it in two or three cases of myonectomy and found it very good. He had never tried it in any other operation, but was sure it would be useful in performing a hysterectomy or any operation. Dr J F CUNNINGHAM said that he had seen Dr Bonney himself using this instrument, and there had been no haemorrhage at all during the operation. He believed that the instrument was not sufficiently used.

#### Interstitial Tubal Pregnancy

Dr BETHEL SOLOMONS showed a specimen of interstitial tubal pregnancy and gave the following clinical details:

A woman aged 30 had been married three years and had two children, the last having been born in 1925. There had been no miscarriages. There had been amenorrhoea for a month and she then noticed a blood stained discharge from the vagina. Two days later she passed a more solid substance per vaginam and since then a reddish brown discharge had persisted. There had been no previous operations or illnesses. She had menstruated every twenty-nine days for four or five days, heavily, without intermenstrual pain or discharge. There was a swelling in the right lower abdominal region, close to the uterus, and a diagnosis of broad ligament tumour was made. The urubimogen test was negative. The abdomen was opened and a tumour the size of a tangerine orange was found to occupy the right corner of the uterus, external

of tumour and a thinness of tube. Its colour was bluish with patches of yellow here and there. The uterine vessels were controlled with Brunner's forceps and the ovary with ring forceps. The portion of the uterus involved was resected wide of the tumour. The uterine cavity was opened and the incision closed with two rows of interrupted catgut. The round ligament was brought over the uterine wound and the abdomen was closed.

The tumour on section presented a cystic cavity about the size of a plum which was apparently the ovum surrounded by a blood clot about three-eighths of an inch thick. In section through the blood clot were scattered shadowy villi. The tumour was an interstitial pregnancy which had not ruptured but had been dead for some time. The patient was discharged in good condition.

Dr. Solomon said it was believed that an interstitial pregnancy never aborted into the uterine cavity but that the most usual thing to happen was rupture into the abdominal cavity with severe, if not fatal, haemorrhage. It was impossible in most instances to make a definite diagnosis of interstitial pregnancy although a swelling either posteriorly in the region of the tube in close proximity to the uterus, might suggest the diagnosis.

Dr. D. C. Macmillan said that he recollected a case in the Rotunda Hospital once years ago which was thought to be an interstitial pregnancy but which had turned out to be a tubal pregnancy very near the uterus. He thought that this was an excellent case for demonstrating the utility of Brunner's plug. Dr. C. Brunner asked what had determined the necessity for operation in this case. Had there been an excessive pain or only the persistent discharge? Dr. A. H. Davidson referred to a paper by Rubin in which he described how tubal pregnancy might be explained possibly by the fact that the ovum was being driven along the tube at an early period of the menstrual cycle and the peristaltic movements of the tube were not sufficient for the ovum was arrested and a tubal pregnancy developed.

Dr. Solomon, in reply, said that the patient had been operated on because of the history of morning sickness and slight haemorrhage.

#### Adenocarcinoma of the Uterine Body

Dr. Solomon showed three specimens of adenocarcinoma of the body of the uterus.

The first was in an unmarried woman aged 43 who complained of pruritus vulvae, slight leucorrhoea and pruritus mammae. Apart from backache her general health was good. She was a virgin intacta and examination under anaesthetic revealed a small fibroid uterus which was removed.

The second patient was aged 55 and sterile. She complained of recurrence of menstruation after amenorrhoea for two years. In addition to this was a certain amount of yellow discharge. Both breasts had been removed for malignant disease—one eight years and the other five and a half years ago. She had no other complaint and had not lost weight. There was a slightly enlarged uterus in good position. A diagnostic curettage revealed adenocarcinoma and hysterectomy was performed.

The third patient was a single woman aged 53 who complained of constant haemorrhage for the past two years. Regular menstruation had ceased a year previous to the start of the haemorrhage. Her only former illness was rheumatism. Her weight was very anæmic but had not lost weight. The uterus was small and in good position. A diagnostic curettage disclosed adenocarcinoma and hysterectomy was performed.

Dr. Solomon commented on the fact that the only complaint of note in the first case was a mucous discharge and pruritus. In the second case that both breasts had been removed but he did not believe they had anything to do with the present trouble. He noted that fibromatous were present in two cases and that the uterus was small. Nulliparity was nearly always present in the cases, and the age incidence was what was expected. He commented on the necessity for a diagnostic curettage in cases of irregular haemorrhage about the menopause and had found that the most usual differential diagnosis was between simple endometritis and simple carcinoma. The microscopic report of the three specimens was to the effect that the gland structure was very well marked and in some places had infiltrated the muscle wall to a considerable extent in some the epithelial cells appeared normal but in the uterine it was degenerated and necrotic. There was much round-celled infiltration. The condition was an adenocarcinoma of high maturity and consequently of low malignancy.

Dr. D. C. Macmillan agreed about the value of a diagnostic curettage in these cases of haemorrhage occurring after the menopause. Sometimes the report received on the specimen was that it was non-malignant but after it was

malignant. He himself had had a similar case two or three years ago in which the breasts had been amputated for carcinoma previously. A tumour in the pelvis was found to be very densely adherent and proved to be carcinoma of the ovary. He asked if a Wertheim operation had been contemplated in any of these cases, and mentioned a case which he had seen some months ago with ordinary multiple fibroids, in which he had performed a supravaginal hysterectomy, and had received a report of adenocarcinoma. Referring to the after-treatment of these cases he asked if Dr. Solomon gave morphine, and if there was subsequent constipation.

Dr. Davidson thought the important thing in adenocarcinoma of the body of the uterus was the diagnosis. These cases frequently did not begin to show symptoms till the condition was advanced. An important fact to remember when examining these patients was that the condition usually occurred after the menopause. At this time the uterus was very atrophic and it was easy to be misled by finding a small uterus. It should be borne in mind that cancer of the uterus might be present in cases where the tumour was very small. In the cases it was necessary to use the curette with care since sometimes it entered the wall of the uterus and perforation occurred with disastrous results. He drew attention to the necessity for examining the groins in the cases for the possible presence of enlarged carcinomatous glands.

Dr. J. T. Cunningham asked if in the case described by Dr. Solomon there had been any haemorrhage and if not why operation was performed. The patient apparently had had a small movement of the uterus but he wondered if there had been any other reason for deciding on an operation.

Dr. Solomon in reply said he considered that total hysterectomy and not Wertheim's operation should be performed for cancer of the body of the uterus. He had never found the inguinal glands enlarged. He operated on the first case because he believed that the disease in the uterus was producing the mucous discharge which caused the pruritus. He was a strong believer in the value of morphine after operations.

#### JAMES MACKENZIE INSTITUTE

On November 29th at the James Mackenzie Institute for Clinical Research St. Andrews Dr. Forster Spriggs in a paper on the early symptoms of cancer of the stomach and that study of a series of patients showed that the onset of the disease was appreciable in most cases. In two-thirds of them the symptoms dated back more than nine months on the average an interval of a year or more having elapsed before a full investigation was made. Analysis of the symptoms in order of frequency and of the order in which they arose showed that the most important early symptoms were fullness, discomfort or pain not severe or continuous but recurring persistently and arising in a middle-aged or elderly person. The next symptoms in order of frequency and importance were lack of appetite, dislike of food, nausea with retching loss of weight. Haemorrhage might be a first symptom. The pain or discomfort was often relieved by food in cancer of the pylorus and of the body of the stomach. Among the cardinal symptoms of cancer was pain and tumour were late results and pain was so variable that no security could be gained from its absence. Anaemia was usual though in exceptional cases the blood might be normal up to a short time before death. When cancer arose in the subject of ulcer or other form of dyspepsia there was often a recognizable change in the symptom. The earliest objective sign of cancer was probably local arrest of the wave in the stomach as shown by x-ray. This was demonstrated by the superposition of x-ray films taken at such an angle that the lesion was in profile. The sign was common to cancer, ulcer and fixation by adhesions. A filling defect or mud induration at the edge of an ulcer as shown by bending over the shadow suggested cancer. The tests for achylia and occult blood were of great value. If there was a pathological and clinical suspicion of cancer the first operation to make sure was much smaller than the rest was to clamp the caecum. It was wrong to treat indigestion for

any length of time in a middle-aged person without taking steps to exclude cancer. Resection of the pylorus or the body of the stomach, if undertaken at an early stage, could be performed successfully. In conclusion, Dr. Spriggs declared that the fight against cancer was a fight for early diagnosis. If the delay between the onset of symptoms and investigation could be avoided, life could be saved in a great proportion of cases. Further progress depended in present upon the profession and the public becoming alive to the fact that earlier diagnosis could and should be made.

## Reviews.

### EMERGENCIES IN GENERAL PRACTICE

It is a truism to say that as each year passes the perceptive citizen becomes more exposed to risk of life and limb in going about his ordinary affairs. Quite apart from the enormous increase of mechanically propelled traffic, even such an apparently innocent amusement as "listening in" may be fraught with the gravest danger, as one of two recent accidents have testified. It is incumbent upon every member of the medical profession to arm himself that he may deal promptly and efficiently with the many and various emergencies which sooner or later he may encounter either in the routine of his duties or as a casual passer-by. For these reasons the appearance of such a book as *Emergencies of a General Practice*,<sup>1</sup> by two American practitioners, the late Dr. Nathan Clark Moulton and Dr. Asa Corcoran, is cordially welcome. Every conceivable emergency to tubal rupture, from poisoning by ivy to fractures of the long bones. The advice given is dogmatic and practical, from the seasoned experience of men who have done the things they describe and not simply read about them. Of necessity in a book of this kind, the wider considerations can only briefly be touched upon, but useful references to original papers are given so that those interested can probe more deeply.

Where necessary the authors do not hesitate to indicate when in their view a method of treatment is beyond the skill of the ordinary general practitioner, but while they urge the supreme importance of the doctor recognizing his limitations at all times, they never fail to encourage him to increase his sphere of usefulness by "learning to do many things better." They say in the preface "One cannot but feel that the general practitioner is sending too much work to the specialist, that the good old family doctor is passing." As in the United States, so it is, we speak as to the harm done in workshops and elsewhere by the hybrid darning on of tincture of iodine to cuts and injuries by unskilled—and unwashed—hands and then hoping for the best.

The subject of shock, from both the theoretical and practical aspects, is very well epitomized. In describing the treatment of shock no note that no mention is made of pituitary extract—a useful aid, if not of absolutely supreme importance. A flat contradiction has been allowed to creep in, in the discussion of the treatment of antio infections of the knee-joint. On one page active movements are extolled and the statement is made "Recovery is quicker and the function of the joint much better than under the old immobilization treatment. This method is in use by most surgeons." On turning the page we are faced with the remark that "immobilization of the joint is of the greatest importance." The value of insulin in diabetic coma and the method of using it deserve more than the casual reference made by the authors. One other position on her right side." These slight blemishes do but confirm our opinion of the book's very high standard of general excellence. It is not only useful, but inspiring, and certainly one which should be read by every doctor who

<sup>1</sup> *Emergencies of a General Practice*. By the late Nathan Clark Moulton and Asa Corcoran. W. B. Saunders Co., Philadelphia, 1927. (6 x 9 1/2 in.) 1 P. 541. 311 figures. 42s net.)

is not a pure specialist or a fashionable signpost therapist. The illustrations, on the whole, are good, but more have been employed to depict the use of zinc stripping instead of bandages than seems quite necessary.

### RHEUMATISM AND GOUT
